A TERM has long been needed to denote direction along a line, as is so frequently needed in speaking of electric currents, magnetic forces, and many other physical quantities. Such a term has now been coined by the same accomplished hand to which we owe the useful works "torque," "dyne," and "numeric"—Prof. JAMES THOMSON, of Glasgow. The new word is "*ward*," a substantive noun signifying "line and direction in a line: that which is represented ordinarily by a barbed arrow." Sir WILLIAM THOMSON, writing in the *Philosophical Magazine*, uses his brother's term as follows:—"I now define the ward of magnetisation as the ward in which the magnetising force urges a portion of the ideal northern magnetic matter or northern polarity."

NEW processes for the electro-deposition of metals are always worth a trial, especially one for the deposition of iron. The following recipe is given by Messrs. BARTHEL and MÖLLER, of Hamburg. Six hundred grammes of ferrous sulphate ($FeSO_4$) are dissolved in five litres of water; to this is added a solution of 2,400 grammes of carbonate of soda (Na_2CO_3) in five litres of water. The resulting precipitate of ferrous carbonate, $FeCO_3$, is then re-dissolved by the addition in small quantities of strong sulphuric acid, until the precipitate is just dissolved, when the fluid will show a green colour; it is then diluted to twenty litres by adding water. The solution must be faintly acid, turning blue litmus paper deep claret colour, but not red. An iron anode is used.

IN addition to the course of lectures on "Electrical Technology," the syllabus of which we give in another column, Prof. AYRTON proposes between now and Easter to give a special lecture and laboratory course for elemementary school teachers. The introduction of physics into the curriculum of our elementary schools is likely to prove an innovation of somewhat doubtful value, unless the subject is taught in a more practical manner than is the case in the majority of our higher schools. With Prof. AYRTON, however, to teach the teachers, there is no danger of the practical side being lost sight of, and from the teaching of the elements of physics in a common-sense manner nothing but good can come. This course commences on January 25th, and will comprise nine lectures.

Western Union Telegraph Company.—The cables of this company are now repaired.

The Baudot Telegraph.—The line connecting Algiers and Oran is being fitted with the Baudot apparatus.

The Frankfort Exhibition.—The International Electrical Exhibition has been postponed until the spring of 1891.

Paris.—The sum of 32,000 francs was voted at the last meeting of the Municipal Council to defray the expense of fitting the Caisse Municipale with the electric light.

The Commercial Cable Company.—Mr. J. W. Mackay this year gave his usual Christmas present of half-a-month's pay to every member of the staff of the Commercial Cable Company.

The Royal Society.—Among the Papers down for reading at yesterday's meeting was one by Dr. J. A. Fleming, "On Electric Discharge between Electrodes at Different Temperatures in Air and in High Vacua."

Northfleet.—At the last meeting of the Local Board, the Clerk informed the Board that the Gas Company's Bill, of which they gave notice, sought powers to light Rosherville by electricity, in addition to other matters.

Salonica.—A powerful group of financiers is endeavouring to obtain concessions for the electric lighting of Salonica and other Turkish seaports. The proposals of the syndicate are strongly supported by the Government officials.

Keswick.—The Keswick Electric Light Company commenced to supply current to the consumers in the centre of the town and at the Keswick Hotel on Monday night. The light was very steady, and gave the greatest satisfaction.

Torquay.—The Torquay Local Board have decided to oppose the applications of the Devon and Cornwall Electricity Supply Company and the Municipal Electric Light and Power Corporation, with a view to gain time to consider as to the advisability of applying for powers themselves.

A Correction.—The Glasgow Central Station of Muir, Mavor, and Coulson (Limited), which appeared among those in progress in the list on p. 223 of our last issue should have been placed amongst those in operation. Muir, Mavor, and Coulson (Limited) also have a low-tension station in operation in Glasgow.

Birmingham.—The Birmingham Electric Supply Company, which has undertaken to carry out the necessary work in connection with the Provisional Order obtained last Session by Messrs. Chamberlain and Hookham, have decided to at once erect a 5,000-light station. The low-tension system will be employed.

St. Luke's Vestry.—At the last meeting of this Vestry the Clerk read a letter from Messrs. Bircham and Co., on behalf of the Metropolitan Electric Supply Company, stating that it is not the intention of the company to proceed with their proposed application to the Board of Trade to supply electric light in the parish.

The Brussels Tramways.—M. Michelet, manager of the Société des Tramways Bruxellois, has resigned, owing to differences with his colleagues on the question of the employment of electricity. It is thought that the result of M. Michelet's resignation will be a large development of electric traction on the Brussels lines.

The India Rubber Market.—Cablegrams from Brazil say that the rubber market is liable to give out entirely, as the supply on hand is very small. Rubber has advanced from 2,200 to 2,400 reis. The stock is 5,000,000lb. less than it was a year ago, showing that the consumption of rubber is exceeding the production.

The Electric Meter Competition.—*L'Électricien* announces that the report of the special committee charged with examining the electric meters sent in to compete for the municipal prize of 10,000 francs will shortly be laid before the Municipal Council. The special committee, it will be remembered, consisted of MM. Mascart, Hospitalier, Vaillant, Lyon-Alèmand, and Pottier.

Destruction of an Edison Station.—The down-town station of the Edison Electric Lighting Company of New York caught fire on Thursday morning last week, and was completely destroyed, entailing a loss of $100,000 upon the Company. The station occupied two four-story buildings, and supplied current to 18,000 lights. The fire started in the dynamo room, but how it broke out is unknown.

Bridlington Local Board.—At a meeting of this Board on Tuesday last, the Building and Lighting Committee reported

Digitized by Google

that at a meeting held for the purpose of considering the best means of lighting the public streets and places within the district, it was decided to recommend the Board to advertise for tenders for lighting the district either by coal gas or electricity. The report of the Committee was carried unanimously.

Otto von Guericke's Air Pump.—At the last meeting of the Berlin Physical Society the President exhibited the air pump constructed by Otto von Guericke in 1675, which had recently been acquired by the Physical Society. This pump is still in a thoroughly workable condition, with the exception of the glass vessel, which has been renewed. The pressure in this receiver could be reduced to 20mm. of mercury by means of the pump.

The 1889 Prizes of the Academie des Sciences.—At the annual meeting of the Académie des Sciences on December 30th it was announced that the La Caze prize had been awarded Dr. Hertz for his discovery of electric undulations, and of the curious effect of the ultra-violet rays on the electric charge. The Montyon prize for physiological researches was awarded to M. d'Arsonval, mainly on account of his electro-physiological work.

The Telegraph in Bavaria.—The fortieth anniversary of the inauguration of the first Bavarian telegraph line was celebrated at Munich on December 24th. This line was ninety miles long and connected Munich with Salzburg. It was commenced in 1848, completed on November 9, 1849, officially inaugurated on December 24th of the same year, and opened to the public on January 15, 1850. Within ten years of the latter date the line mileage in Bavaria amounted to nearly 4,000.

Eastbourne.—A meeting of the Town Council was held on Monday to consider the recommendation of the Special Committee that the Town Council should apply in the Session of 1891 for a Provisional Order, and refuse their consent to the granting of the proposed Provisional Order of the Eastbourne Electric Light Company. After an animated discussion, it was decided to refer the question back to the Committee and to hold a special meeting of the Council at an early date to finally decide the matter.

The Payen Accumulator.—In preparing his plates, M. Payen prepares an intimate mixture of asbestos fibre and fused chloride of lead and then pours the molten mass into a mould. The material crystallises as it cools, and a chloride of lead plate bound together by the asbestos fibre is the result. The plates are formed in two distinct operations. The chloride of lead is first of all transformed into spongy lead by being made the cathode to an ordinary lead plate as anode. The spongy lead plates are next formed in the ordinary manner, and are then ready to be used.

Berlin.—The Allgemeiner Electricitäts Gesellschaft is extending its conductor system by about 50 kilometres, and a new conductor, consisting of bare copper rods fixed on porcelain insulators in special channels, is to be used. The company is of opinion that this system ensures greater durability as compared with cables, simplicity in extending the network, cheapness, and high insulation. A further advantage claimed is that this conductor will be free to expand and contract owing to the changes of temperature due to the passage of the current, without disturbing the insulation.

Aberdeen.—At the meeting of the Town Council on Monday the report of the deputation on electric lighting was laid on the table. Mr. Cook, who was one of the deputation, said they would have observed that in America the electric lighting had been going out. He had no fear that their gas undertaking, in which they were all so deeply interested, would be imperilled in any way for a great number of years to come. He recommended that the report should be adopted, and that they take power to do a certain thing in a given time, but that would not compel them to do anything at all unless they chose. The report was adopted.

The Notting Hill Electric Lighting Company.—This company, as will be seen by our advertisement columns, is about to come before the public for the subscription of its capital. A compact residential district in the neighbourhood of Holland Park, the rateable value of which is nearly £400,000, was allotted to this company last Session. The chairman of the company is Mr. William Crookes, F.R.S., Mr. R. E. Crompton acts as consulting engineer, and the system employed will be a low-tension one. At the present moment the Notting Hill Company is the only one which has electric lighting powers within this area.

The Clermont-Ferrand Electric Tramway.—An electric tramway connecting Clermont-Ferrand with Royat has recently come into operation. The line is 1½ mile long, and there are 13 stations. Passengers are allowed, for an extra charge of 25 centimes, to carry 50 kilogrammes of luggage. The generating plant comprises a 150 horse-power Farcot engine, a 6-pole separately excited Thury dynamo, giving 350 amperes and 300 volts at 375 revolutions. The current is taken to the cars by an overhead conductor, the rails acting as return. Each car is driven by a 40 horse-power Thury motor. The normal speed is eight miles an hour.

Dundee.—A meeting of the Special Committee of the Town Council, Police Commission, and Gas Commission on the subject of electric lighting was held on Monday. A long explanatory statement by Prof. Ewing was submitted, and it was reported that the only Provisional Order lodged with reference to Dundee, in addition to that of the Gas Commission, was that by the House-to-House Company. The clerk was instructed to issue a circular to the consumers who took £5 worth of gas and upwards, with the view of eliciting whether they would be disposed to take electricity in place of gas if the price of electricity did not exceed once and a-half or twice the price of gas.

The Actino-Electric Effect of the Ultra-Violet Rays.—Among the many investigators into this subject is M. Righi, who attributes the effects to the convection of negative electricity, the charge being separated from the illuminated surface under the influence of the ultra-violet rays, and carried in the direction of the lines of force. M. Righi has shown the existence of this convection by means of aluminium vanes, which were made to move in presence of the rays. The rate of convection, which depends on the capacity of the conductor per unit surface, varied in M. Righi's experiments from 50 to 150 metres per second. M. Righi also succeeded in deviating the convection streams by means of an air blast.

An Electric Gas Governor.—The following is a description of an electrical device for regulating the pressure of the gas in house mains, which was to be seen at work in several parts of the Paris Exhibition. The apparatus consists of an indicating dial and a pair of electro-magnets, the armatures of which actuate a ratchet wheel in opposite directions, closing or opening the gas admission valve as may be necessary. The index of the dial is in connection with one pole of a battery, the other pole being connected through the two electro-magnets to two contacts on the dial. These contacts can be arranged so that a variation in either direction from the standard pressure will bring the lower end of the index against one or the other of the contacts, and the circuit being closed one of the electro-magnets comes into play, and actuates the admission valve. This form of governor is said to act rapidly and effectually.

An Electrical Apparatus for Determining Melting Points.—The exact determination of the fusing point of oily substances, such as certain kinds of wax, is very difficult, owing to the fact that they pass through an intermediate viscous stage. An electrical apparatus for this purpose has been devised by M. Ferdinand Jean, manager of the Paris Bourse de Commerce, and it was exhibited by him at the recent International Congress of Chemists. The apparatus consists of a U-shaped tube, spread out at one end to receive a sample of the substance to be tested, which is covered with a layer of mercury. Two platinum wires, forming part of an electric-bell circuit, are introduced into each half of the tube, and the tube is then placed in a water bath. When the substance attains its melting temperature it flows into the lower portion of the tube, and the mercury completes the electric-bell circuit. The temperature shown by the thermometer in the bath at the moment the bell rings is taken as the melting point of the substance.

Lightning in Mines.—A short Paper was recently read before the Mining Institute of Scotland by Mr. David Smith, describing the effects of lightning which entered the Drumsmudden pit workings in November of last year. The flash, it appears, was

Digitized by Google

observed when the ascending cage was within twenty yards from the surface. The engineman was rendered powerless, but had the presence of mind to throw himself on the brake lever and so stop the engine. The chainman, signal boy, and other boys also experienced severe shocks, but beyond this no harm was done. During the occurrence a thunderstorm of unusual severity was raging, and balls of fire were seen leaping between the haulage rope and the rails. In the discussion which followed the reading of the Paper several cases were mentioned in which the same phenomena were observed: the explosion of fire-damp in a disused lead mine near Hexham was thought to have been caused by lightning, and the Risca colliery explosion in 1880 occurred during a heavy thunderstorm.

Lectures on Electrical Technology.—The following is the syllabus of the course of lectures on electrical technology which is to be given by Prof. Ayrton on Mondays and Wednesdays, at the Central Institution, during the spring term. These lectures commence on Wednesday next, and as the hour is four in the afternoon, it is anticipated that a large number of professional men and others will attend:—Accumulators: Construction; Testing; Storing Capacity; Output; Life. Electric Lamps, Arc and Incandescent: Construction; Regulation; Testing; Efficiency; Life. Introduction to the Study of Transformers: Direct Current; Alternate Current; Testing; Power; Efficiency. Electric Traction: with Accumulators; with a Stationary Conductor. Absolute Block. Telpherage. The Distribution of Energy Electrically. Practical Use of Accumulators and Transformers, in electric distribution. Comparison of the Various Systems of Distribution and their Relative Advantages. Electric Lighting by the Parallel, Series, and Parallel-Series systems.

Severe Thunderstorms.—On Saturday night last, various parts of Ireland were visited by a storm of unusual severity, accompanied in many instances by thunder and lightning. The Protestant church at Birr was struck by lightning. The porch and pinnacle were torn away. A large hole was made in the roof, and a stone was torn from the side wall and thrown across the church. The interior of the building was completely wrecked. The cottage of a farmer named M'Cole, near Cardonagh, county Donegal, was struck. The tenant's wife and daughter were both killed, while he and his son were injured seriously; the son subsequently succumbed to his injuries. Early on Monday morning several districts in the north of Scotland were visited by a very alarming thunderstorm. At Pitlochry, Crieff, and other parts of Perthshire, the storm was greatly felt. A severe thunderstorm also prevailed over Anglesey and Carnarvonshire. A house near Beaumaris was struck by lightning and demolished. Of the six inmates, five escaped without injury, but the other was hurt by falling fragments.

Tinting Incandescent Lamp Bulbs.—The following recipe is due to Mr. Arthur S. Huey, of Minneapolis:—Prepare the glass by thoroughly washing in soap and water and drying. Then dip in bath (made by beating up the whites of two eggs in one and a-half pounds or pints of water, and filtering) and hang up to dry. Dissolve the aniline colour in photographer's common collodion. Red or blue aniline will form clear solutions, while the green solution will require filtering. Yellow aniline forms a handsome colour, but the surface of the glass presents a frosted appearance after the application. Violet and purple colours may be obtained by combining red and blue in different quantities. When the solution is ready, dip the prepared glass bulbs therein; hang up to dry, and finally pass a current through the bulb for half an hour, that the heat thus generated may harden the coating of the collodion, or place in a current of air. The preparation can easily be removed with alcohol or sulphuric ether, but is not affected by water. Experience has shown that the best results are obtained by not using too much aniline. Make the colour light rather than deep, and apply two or three coats.

St. Margaret's and St. John's (Westminster) Vestry.—At a meeting of this vestry on Wednesday, the Works Committee reported that they had further considered the question of electric lighting in the united parishes. In view of the London Electric Supply Corporation and the Westminster Electric Supply Corporation both having power to lay mains in Victoria-street, some correspondence had taken place with the former as to whether they would be willing to wait until the Westminster Corporation were ready, in order that the two mains might be laid at the same time, and thus minimise the inconvenience to the public by the interference with the pavements and crossings. The London company, however, declined to do so, on the grounds that whilst they wished to complete the work as soon as possible, the Westminster Company might be months before they were ready. The London Company's mains will consist of a concentric cable covered with two sheathings of steel, flexible, quickly laid, and only requiring to be placed 4in under the flagstones, but the Westminster company proposed putting down a brick or concrete culvert, necessarily requiring a trench of considerable size, and taking time to construct. The London Company had begun operations. The report was adopted.

A Recording Compass.—An electrical recording alarm compass has been devised by Mr. H. A. Chase, electrician to the Boston Police Signal Service. The compass is constructed by Messrs. J. P. Cushing and Co., of that city, and consists of two parts, the binnacle and the recorder. The binnacle contains a Ritchie compass, modified to suit requirements, and is located in the pilot house, while the recording and course-directing device is placed aft in the main cabin, the two being connected by a flexible wire cable. The compass has contacts for each point of the compass, a separate wire connecting each point with the recorder located in the cabin. This latter device consists of a number of magnets, one for each point of the compass, and a recording sheet properly ruled to correspond with the points of the compass and time of day, actuated by clockwork at the rate of 18in. for every watch of four hours' duration. Each magnet is connected to a prick point, and every time the circuit of a magnet is closed at the compass, the point is operated to perforate the paper. Connected with the course-selecting device are port and starboard alarm bells, which are sounded in case the vessel deviates any predetermined number of points from her course. The circuit for actuating the entire mechanism is run by means of Gassner dry batteries.

A Simple Method of Measuring Contact Differences of Potential.—Prof. Righi has already shown that ultra-violet radiations reduce to the same potential two conductors, a plate and a piece of netting, applied to each other, the rays being thrown on the netting side. He now points out that this suggests a very simple and convenient way of measuring differences of potential of contact. Note the deflection of an electrometer connected with the plate (the netting being permanently connected with earth); then, having connected the electrometer for an instant with earth, make the radiations act a sufficient time. Prof. Righi used a zinc electric lamp, and the metals examined were placed in some cases in a bell jar, to which some gas or vapour was admitted. From measurements of different plates with the same metallic net (copper, zinc, or platinum), the differences of potential of pairs of metals could be deduced. Prof. Righi found the differences sensibly the same in dry and moist air and in carbonic anhydride; but with hydrogen very different values (from those in air) appeared, where one of the metals examined was platinum, palladium, nickel, or iron (doubtless owing to absorption). In ammonia all the metals, examined with zinc net, seemed to have become less oxidisable; and in coal gas, carbon and platinum behave like more oxidisable metals.

The Electrolysis of Cryolite.—In a paper on "Electrolysis of Cryolite," in the *Journal* of the Chemical Society, Mr. W. Hampe says:—"By the electrolysis of cryolite, or mixtures of cryolite and sodium chloride, some investigators have obtained aluminium bronze, others have not; the success of the former is due to the use of a solid copper negative electrode, and the failure of the latter to the use of molten copper for that purpose. The author's experiments indicate that when the electrolysis takes place near the melting point of copper,

Digitized by Google

bubbles of sodium vapour come off and burn at the surface; any aluminium set free is in such a finely divided state that it almost all combines with the fused cryolite to form the sub-fluoride; but when the electrolysis is conducted at lower temperatures, the sodium separates in a liquid state and gives rise to larger aggregations of aluminium, which consequently expose a smaller proportion of surface, and are less rapidly attacked by the molten cryolite; nevertheless, some is attacked, and the yield of aluminium alloyed with the copper is always much below theory. The alloy has a lower melting point than copper, and therefore melts off the electrode and drops to the bottom of the crucible. By mixing salt with the cryolite, the melting point of the latter is lowered, and the electrolysis may be conducted at a lower temperature.

The Edinburgh Exhibition.—The Executive Council have decided to finally close the list of applications for space on the 15th inst., when allotment will be proceeded with. Amongst the electrical exhibitors are Sir William Thomson, Mr. W. H. Preece, Mr. Edison, the General Post Office, Edison-Swan Company, Laing, Wharton, and Down; Brush Company, Paterson and Cooper, United Electrical Engineering Company, King, Brown, and Co.; Muir, Mavor, and Coulson (Limited); Elmore Copper Depositing Company, Thomson-Houston Welding Company, Newall Engine Company, Robey and Co., Electric Traction Company, Ernest Scott and Co., Ronald Scott, Woodhouse and Rawson, Buller, Jobson, and Co.; W. T. Glover and Co., National Telephone Company, Consolidated Telephone Construction Company, Colonel Gouraud, Gent and Co., Exchange Telegraph Company, Eastern Telegraph Company, &c., &c. The Decauville Company propose to show a narrow-gauge railway in operation, but worked by electricity in lieu of steam. The Executive Council have arranged with Messrs. Immisch and Co. for a 10 minutes service of electric launches on the Union Canal between Fountain Bridge and the Exhibition. In addition to the British Electrical contingent, about 150 electrical exhibits are expected from France, where the Government have officially recognised the Exhibition, and considerable numbers from other foreign countries.

The Fiske Range and Position Finder.—The principle of this apparatus consists in the determination of a fractional portion of a conducting body bearing in length a ratio to the angle included between two lines of sight directed upon some distant object, and the measurement of the electrical resistance of this length. The salient features of the apparatus consist in the determining of the exact range of any distant object by keeping trained upon it a telescope, which in moving carries along with it a dial parallel with the telescope. This dial is electrically connected with a graduated arc over which it moves, and by means of ranging angles registers accurately the distance of the object from the apparatus. An observer, then, stationed at the galvanometer, and at one of the points of resistance, can, by noting the galvanometer and adjusting the resistance in the usual way, determine the resistance equilibrating any portion of the arm along the arc, and so discover the angle of adjustment of this arc; or, having adjusted one of the points of resistance at some given figure, the observer may, by simply noting the galvanometer or any other suitable indicating device, visible or audible, determine when the dial is placed at a desired angle corresponding to the adjusted resistance, and this indicating device is obviously at the place where the moving arm is situated, so that the operator then knows when he has placed the arm at the predetermined point, or at the distant station, so that the operator in charge of the resistance point can know that the arm has been properly adjusted; or two indicating devices in the same circuit may give warning to both operators, as above, simultaneously. By this means the elevation or training of a gun may be determined or recognised from a distant point.

Deep-Sea Fishing by Means of the Electric Light.—In the investigations that were undertaken by the Prince of Monaco in deep-sea soundings an ingenious method was adopted to obtain specimens of the living creatures existing at the bottom of the ocean. The apparatus used was shown at the Paris Exhibition. The cage in which the submarine animals were caught, according to *Le Genie Civil*, consisted of a cylinder of wire having three conical entrances, like those of a lobster pot, and weighted for submersion with detachable weights. It was, however, very unlikely that at these immense depths, where the darkness is practically total, any fish would voluntarily find their way into the trap, and steps were taken to attract them by a light placed inside it. Obviously, no light was available but an electric light, but to get an electric light to burn a mile or two under water was not easy. The only resource was to supply the incandescent wire from a battery in the trap. Here, however, another difficulty appeared. It was necessary to enclose the battery, which had to be of considerable power, in a box of some kind, and as the hydrostatic pressure at such depths was six or seven hundred pounds per square inch, it was found impossible to make a box which was not crushed before it reached its destination. At last, however, this trouble was overcome by the curious device of connecting the box with a balloon. The balloon was made of cloth dipped in indiarubber, and so arranged that the air in it was in communication with that in the battery-box. On sinking the apparatus, the hydrostatic pressure, being virtually uniform all round the balloon, compressed it equally on all sides, forcing the air out of it into the battery-box, until the pressure inside the box and balloon exactly balanced the pressure outside. This process went on to any extent, so that at the bottom of the sea, although the balloon was reduced by the enormous force exerted on it to a small fraction of its original size, it still kept the internal and external pressures equal. On raising the apparatus again it expanded as the pressure diminished, and brought the battery-box to the surface uninjured. So successful was this device, that, not content with capturing deep-sea fish, the Prince and his assistants propose on their next expedition to send down a photographic apparatus and bring back negatives of the bottom of the ocean, as seen by the electric light.

Ships Struck by Lightning.—Up to 1820, when Sir W. Snow Harris commenced his agitation for the use of lightning conductors at sea, ships had practically been without any such protection. It is, therefore, not surprising to find that in the course of about fifty years—from 1793 to 1840—over 200 ships had been struck by lightning. Between 1810 and 1815 the Royal Navy suffered severely, for damage was done by lightning to no fewer than 35 line of battle ships, 13 frigates, and 10 sloops. It was estimated that in 22 years—from 1793 to 1815—the spars of all kinds shattered by lightning and rendered useless were worth about £72,000. In 1813 no fewer than five out of thirteen line of battle ships cruising off the Rhone were struck by lightning on the same night. In some of the old warships an unsuspected source of danger was often to be found. A capstan, having an iron spindle five feet long and six inches in diameter, was placed vertically over the magazine, immediately under which were long metallic bolts, used in the construction of the ship, which passed through the keel into the sea. No arrangement could have been better provided to ensure an explosion. The Harris system of conductors entirely superseded the obsolete chains of Dr. Watson, which stretched from truck to water line when in use, but were more often stowed away. The following are a few instances of the damage caused by lightning to the old badly-protected wooden ships. In April, 1827, the American packet ship "New York," bound to Liverpool from New York, was struck when about 500 miles from the nearest American land. Her old-fashioned conductor was not aloft when she was first struck. Her conductor was then placed in position. It was composed of an iron terminal rod standing up from the royal truck about four feet, to which was attached an iron chain, which trailed in the sea. Again she was struck, and this time the conductor was fused and set the deck on fire, although at the time the rain was falling in torrents. In 1845 a Turkish vessel in the Baltic was struck. Her conductor was aloft, but was not in connection with the sea. A hole, similar to that made by a cannon ball, was made in her side. In 1820, the French corvette "Coquin" had a hole made in her bottom by a stroke of lightning in the Bay of Naples, and but for ready aid must have sunk at her anchors. Finally, the 74-gun ship "Cumberland" required three complete refits and two new mainmasts in the short space of 18 months owing to being repeatedly struck by lightning.

DR. JOHN HOPKINSON.

We publish this week a steel-plate portrait of Dr. JOHN HOPKINSON, F.R.S., the newly-elected President of the Institution of Electrical Engineers.

Dr. John Hopkinson is the eldest son of Mr. Alderman Hopkinson, of Manchester, and he was born in the year 1849. His mother is a daughter of the late John Dewhurst, of Skipton. His education commenced at Linden Grove School, and was afterwards carried on at Queenswood College, but he left there at the early age of fifteen and a-half to enter Owen's College, Manchester, where he remained until he was eighteen, when he entered Trinity College, Cambridge.

In the year 1870 he graduated as Doctor of Science in the University of London, taking as his subject Pure and Applied Mathematics, under the original regulations for that degree. In the following year he graduated at Cambridge as Senior Wrangler and First Smith's Prizeman. These two honours have not very often been obtained by the same man, as the Smith's prize examination is essentially a test of mathematical creative power, or capacity for original work; while the mathematical tripos has always been rather to test a man's capacity of assimilating, and reproducing with accuracy and rapidity, the work of others. By obtaining the first place in both examinations Dr. Hopkinson therefore showed that both his receptive and creative mathematical powers were of a very high order, and this early promise has been amply fulfilled throughout his subsequent career. It is a fact not unworthy of notice in these days, when the fierceness of competition leads many ardent young students to commit the fatal mistake of neglecting physical exercise, that while at Cambridge Dr. Hopkinson was known as a good oarsman and runner, and that he won a footrace only three weeks before the commencement of his tripos.

His first published original investigations, on "Thermodynamics" and on "Internal Friction in the Vibrations of Solids," were contributed to the *Messenger of Mathematics* in 1871; and in this and the following year he read two short Papers on "The Rupture of Iron Wire by a Blow," before the Literary and Philosophical Society of Manchester. In the first of these he showed mathematically that cold increases the tensile strength of iron, and that the reason that it makes it more liable to break under impact is that it increases the elasticity in a higher ratio. This and other results arrived at theoretically were fully confirmed by experiments described in the Papers, which are of considerable importance in the historical consideration of Dr. Hopkinson's scientific work, as they show that from the beginning his tendency was to be attracted by problems of practical importance to engineers, and to employ his mathematical powers to lead him by the shortest road to practically useful results, instead of devoting them to the erection of elaborate structures upon hypothetical foundations.

Early in the year 1872 Dr. Hopkinson accepted the appointment of engineer to Messrs. Chance Brothers and Company's lighthouse works, near Birmingham, at which town he lived until 1878, when he moved to London, and began practice as an engineer on his own account—without, however, giving up his connection with the firm, a connection which still continues, and which has resulted in many improvements in lighthouse work: notably the Group Flashing Apparatus. After his removal to London he very soon became widely known as an expert in patent cases, a branch which still forms an important portion of his practice.

In the year 1877 Sir William Thomson communicated Dr. Hopkinson's first electrical Paper to the Royal Society, and it was published in the *Philosophical Transactions*. The Paper dealt experimentally with the residual charge of the Leyden jar and the dielectric properties of different kinds of glass. In the course of this investigation he showed that the more highly conducting kinds of glass conduct electrolytically even at low temperatures. His next Paper, published in the *Philosophical Transactions* of the same year, "On the Electrostatic Capacity of Glass," contained the results of an investigation carried out in order to test the truth of the conclusion deduced by Maxwell from his electro-magnetic theory of light, that the product of the electrostatic capacity, and the magnetic permeability of a transparent substance should be equal to the square of the refractive index for long waves. The results of the experiments were not in agreement with Maxwell's theoretical conclusion; but, as Dr. Hopkinson pointed out in his Paper, they did not in any way disprove the theory in its more general character. A further investigation communicated to the Royal Society in 1880 confirmed the former results, and showed that if there were any change in the electrostatic capacity of glass with temperature it was not sufficient to reconcile Maxwell's theory with the experimental results. Early in 1881 Dr. Hopkinson read another Paper before the Society, "On the Electrostatic Capacity of Liquids," in which he showed that the hydrocarbon oils behaved as required by Maxwell's theory, while the vegetable and animal oils did not. He pointed out, however, at the conclusion of this passage that the time of disturbance in the actual optical experiment was many thousand million times as short as in the fastest electrical experiment. Two short Papers published in 1878 and 1879 are worthy of passing mention, viz., an experimental Paper "On the Torsional Strain which remains in a Glass Fibre after Release from Twisting Stress," which made a sensible advance in our knowledge of the "elastic fatigue," as it is now called, of glass fibres, and was published in the Royal Society's *Proceedings* for 1878. The second was a mathematical Paper published in *The Messenger of Mathematics* for 1879, on "The Stresses caused in an Elastic Solid by Inequalities of Temperature," which explained by means of the ordinary mathematical theory of elastic solids the liability to breakage under slight stresses of badly-annealed glass vessels or of iron castings withdrawn too soon from the moulds, or made in such forms as to cool at very unequal rates in different portions.

During the years 1879 and 1880 Dr. Hopkinson read two Papers of very exceptional importance, "On Electric Lighting," before the Institution of Mechanical Engineers. In the first of these he described a number of experiments made with a Siemens dynamo to determine its efficiency under varying conditions, and mapped out the relations between E.M.F. and current by means of curves, since called "characteristic curves" by M. Marcel Deprez. It was the nature of these curves which led the author to the discovery of the now well-known "magnetic lag." In the second Paper a number of somewhat similar experiments subsequently made by other observers on Siemens and Gramme dynamos, were mapped out in the same way, and the observations were thus made comparable with one another. It also contained descriptions of a method of measuring the brightness of the electric arc, and the determination of the ratio of the potential difference at the ends of the carbons to the current passing. Early in the year 1883 Dr. Hopkinson made some improvements in the Edison dynamo, which proved to be of exceptional importance as forming the basis of subsequent important improvements in dynamo machinery. In the same year he was appointed to deliver before the Institution of Civil Engineers one of a series of lectures on "The Practical Applications of Electricity." His lecture was entitled "Some Points in Electric Lighting," and in addition to a most masterly general exposition of the subject, he developed in it some very important points, such as the possibility of running two or more alternating machines in parallel, and the relations between the efficiency and the dimensions of a dynamo; and he also pointed out that the fact previously observed by Mr. Shoolbred in experimenting with a Gramme machine, that after a certain current strength had been obtained the E.M.F. began to diminish, could be explained by the approach to magnetic saturation of the iron of the machine. The theory of alternating dynamos was further developed in a Paper on "The Theory of Alternating Currents," read before the Society of Telegraph Engineers in 1884.

In 1885 he read a Paper "On the Quadrant Electrometer" before the Physical Society, in the course of which he pointed out that Maxwell's formula did not represent the facts when the potential of the needle was considerable, an observation which has since been confirmed and further investigated by Prof. Ayrton and some of his pupils. During the same year he con-

Digitized by Google

tributed two Papers to the *Philosophical Magazine*, in the first of which, "On an Unnoticed Danger in Certain Apparatus for Distribution of Electricity," he showed the danger of employing secondary generators of large electrostatic capacity, even if the insulation of the primary circuit and of the primary coils from the secondary ones were perfect. The second one was a theoretical Paper "On the Seat of the Electromotive Forces in a Voltaic Cell."

In 1885 and 1889, Dr. Hopkinson read two very important experimental Papers before the Royal Society, "On the Magnetisation of Iron," and "On the Magnetic and other Physical Properties of Iron at a High Temperature." In 1886 he read a very important Paper before the Royal Society, "On Dynamo Electric Machinery." This Paper contained an account of investigations carried out in conjunction with his brother, Dr. E. Hopkinson, with the object of obtaining an approximately complete construction of the characteristic curve of a dynamo of given form from the ordinary laws of magnetism and the known properties of iron, and to compare the results with the actual "characteristic" of the machine. Another very important Paper, "On the Electrical Illumination of Lighthouses," was read before the Institution of Civil Engineers in 1886.

Dr. Hopkinson was elected as a Fellow of the Royal Society in 1878, and he is a member of the Senate of the London University.

In concluding this brief notice of a brilliant and useful career, which we trust may be continued for many years to come, we would call attention to two important lessons which it teaches to those who hope to become engineers, viz.: the incalculably great advantage to a practical engineer of a thorough mathematical and scientific training, and the fact that a practical engineer while occupying a position in the very front rank of his profession can continue to be an investigator of questions of pure science. Such lessons should, indeed, hardly require enforcing; but unfortunately the voice of ignorance makes up in loudness for what it lacks in weight, and thereby frequently leads the inexperienced astray.

THE RATHBONE PLACE STATION OF THE METROPOLITAN ELECTRIC SUPPLY COMPANY.

The Rathbone-place Station, which now forms one of the Metropolitan Company's generating centres, was started in September, 1887, by Messrs. Pritchett. The first machine employed was a 1,000-light Ferranti alternator of 100 volts E.M.F., Mordey transformers being employed to raise the volts to 2,000, at which pressure the distribution was effected, step-down transformers being employed in the usual way on customers' premises. The Ferranti machine was resorted to pending the completion and delivery of two Mordey alternators—the first of their kind. One of these was started in February, 1888, and the other a little later. In February, 1889, the station was acquired by the Metropolitan Company, who at once proceeded to re-design it, and to substitute Elwell-Parker machines for those *in situ*, the new plant coming into operation in November last.

The station comprises the basement and ground floor of a building 118ft. by 44ft. The dividing flooring between basement and ground floor has been removed, so as to give sufficient height for the new machinery. The hall thus formed is fairly high and airy, but the appearance of the station when complete will be marred to some extent by beams, which are necessary for the stability of the building. A new chimney shaft has been run up to a height of 120ft., the size of the flue being 6ft. × 4ft. The Metropolitan Company have employed white glazed bricks for their shafts, including this of Rathbone-place: they find that a white glazed shaft goes up quite cheerfully, where complaints of unsightliness and difficulties about "ancient lights," &c., would crop up in abundance if it were attempted to put up an ordinary brick shaft in the same spot. Evidence of Mr. Gordon's determination to have the whole of the arrangements well up to date is given by the fact that Dr. Oliver Lodge has been consulted as to the form of lightning conductor most suitable. The form recommended by Dr. Lodge consists of four No. 7 B.W.G. galvanised iron wires fixed with iron staples down the four corners of the chimney; these four wires are connected at four points by similar wires running round the chimney, so that a very large meshed network covering the whole chimney is formed. Each wire has a separate earth, which is made by digging a pit and fixing a 6ft. length of 4in. iron pipe up the centre by stamping in coke all round. The No. 7 iron wire is then leaded into the top of the pipe.

The station is laid out to receive five Babcock and Wilcox boilers, each capable of evaporating 6,000lb. of water per hour, the working pressure being 200lb. per square inch; one heater of the usual vertical type, capable of supplying water at 212° F. for four boilers, in which the feed-water is made to trickle down a number of tubes about 1in. in diameter, which are heated from the outside by contact with the exhaust steam; five Willans triple expansion engines of 200 indicated horse-power, each of which is coupled direct to a 100-unit Elwell-Parker alternator; two Willans engines coupled direct to exciters. The boilers all face towards the yard, beneath which coal bunkers are formed, so that the coal is dumped just where it is wanted without further handling.

Mr. Gordon has taken great care to avoid risk of having to shut down lights from an accident to the steam piping. The main steam pipe runs down one side of the boiler-house, passes completely round the generating-room, and returns along the far ends of the boilers. The two ends of the loop thus formed are connected by cross pipes which pass over each boiler, and into which the boilers deliver their steam. It will be seen that, with this arrangement, by means of stop-valves either side of the loop can be shut off from the live steam and the engines

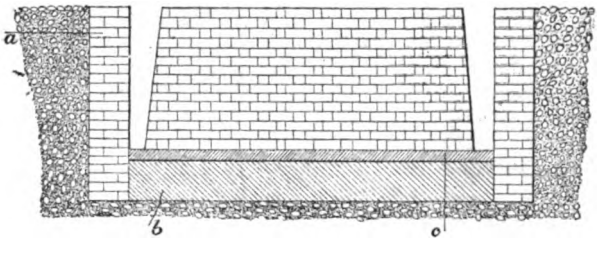

FIG. 1.—Arrangement employed at the Rathbone-place Station to decrease vibration.

fed by means of the other side. Again, if an accident happens to a section of pipe between two engines, this section can be cut out by means of stop-valves, and the engines on one side fed by one side of the loop, and those on the other side of the disabled section can be fed by the other side of the loop. Thus joints can be made, or even a new length of steam pipe inserted, while the system is under steam. The pipes are of wrought iron 9in. in diameter, the flanges are pressed from armour plate by hydraulic machinery, and are screwed and brazed on to the ends of the pipes. All bends are of copper, and the whole of the piping is suspended from the ceiling by iron hangers. Noke's centrifugal separators are employed in the branch connections to each engine.

Another feature of this station is an arrangement to avoid the transmission of vibration either to the station buildings or to other buildings in the neighbourhood. A pit is dug out, of the required depth, the sides of which are lined with four retaining walls; 12in. of concrete is now put in to form a sub-base, on the top of which is laid hair-felt to a thickness of about 2in. The brick or stone base upon which the machinery is bolted, is built upon the hair-felt, a space being left all round between it and the retaining walls. Fig. 1 shows a section of this arrangement—*a* is the retaining wall, *b* is the sub-base, *c* is the hair-felt.

Fig. 2 shows an elevation of an engine and dynamo. The engines are of the Willians type, triple expansion, with the three cylinders ranged one above the other. The cylinders are all single acting, and the cross-head and crank bearings are always in thrust. The cranks are at right angles; they are enclosed, and lubrication is effected by splashing in the now

Digitized by Google

common way. The engines run at 350 revolutions per minute, and normally develop 200 indicated horse-power, with 200lb. initial pressure per square inch. The coupling between engine and dynamo is an ordinary form, and has been rendered sufficiently elastic by the introduction of $\frac{1}{16}$in. thickness of rubber between the two discs.

The dynamo is constructed with stationary armature coils, which are arranged flatwise upon the inner surface of a cylinder, inside of which the field-magnets revolve. The magnets are 5ft. 6in. in diameter, and 1ft. 6in. broad over the polar surfaces; there are 36 poles, and the winding is about 5in. long, and of equal depth to the thickness of the iron core. The armature coils are wound upon wood cores of equal breadth and length to the magnet poles, and each contain 24 turns of copper ribbon $\frac{1}{2}$in. wide. The effective surface of the cylinder occupied by wire is approximately double that occupied by the wood cores. The cylinder in which the armature coils are fixed is formed of laminated iron, the laminæ being held together by cast-iron framework, and lagged over all. The air space, including the depth of the coil, is about $\frac{5}{8}$in. At a speed of 350 revolutions per minute, the machines give 2,000 volts E.M.F. and 230 ∿ per second. The bearing supports are cast with chambers for the circulation of water in case of emergency. The exciting dynamos are direct driven by similar engines to those driving the main dynamos. They run at 470 revolutions per minute, and give 200 amperes at 140 volts E.M.F. The

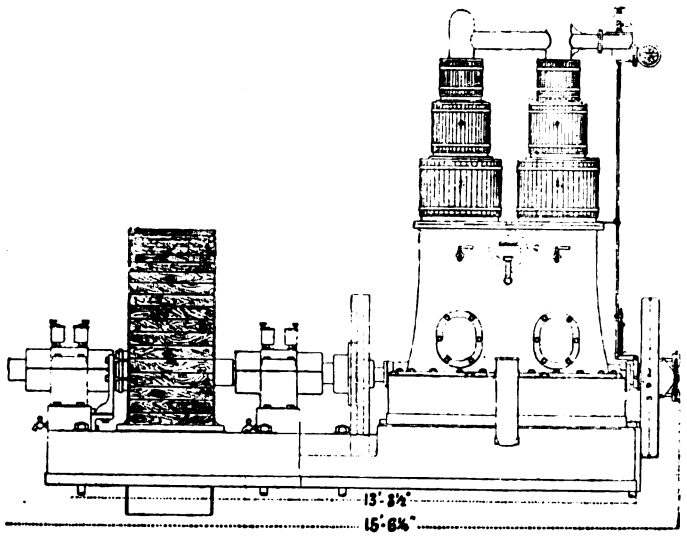

Fig. 2.—Willans Engine coupled direct to Elwell-Parker Alternator.

magnets are compound-wound to give a constant E.M.F. at the dynamo terminals, so that the connection or disconnection of the coils of a dynamo, or the adjustment of resistance in circuit, does not interfere with the adjustment of any other machines which may be running. Each dynamo takes about 40 amperes at 140 volts E.M.F. for its exciting coils. At present it has been found necessary to disconnect the lowest cylinders of the engines and run the exciting sets compound, as the load is so light that a partial vacuum formed in the cylinders and took the thrust off the cranks. It should be mentioned that only two of the five generating sets are as yet in position, and the exciters when at work are only half-loaded. As already indicated, regulation is effected by inserting resistance by hand into the field-magnet circuits according to the readings of a Cardew voltmeter, which is connected across two armature coils, and therefore reads $\frac{1}{18}$th of the full E.M.F., or nominally about 57 volts. The main ammeters are of Evershed's patent, made by W. T. Goolden and Co. The switches for the main circuits consist of 6in. square earthenware slabs or plates, with four projecting brass pins on one side, and a handle on the other. The pins are connected to form two pairs, and fit into four holes in the switch-board. When in position each pair of pins and its connecting piece forms a bridge-connection between the dynamo lead and the line. The switch—which is, of course, double-pole—therefore breaks the connection at four places simultaneously. The main-circuit fuses are enclosed in perforated earthenware cases. The fuse itself consists of a wire about 12in. long, which is connected between two plugs with earthenware handles. Arrangements have been made for observing, by means of a lamp connected to two converters on different dynamos, when the dynamos are in step, with a view to coupling in parallel; but Mr. Tomlinson, to whom we are indebted for most of these particulars, informed us that no attempt had as yet been made to run the alternators in parallel.

ON THE DISCHARGE OF ELECTRIFICATION BY FLAMES.*

BY A. M. WORTHINGTON.

It is well known that an ebonite or glass rod that has been electrified by rubbing is immediately and completely discharged by passing it either through or over a flame—for example, of a Bunsen burner. It is, I think, less well known, though the observation seems to have been made by Priestley,† that the discharge takes place with apparently equal rapidity if the rod be held at the side of, or even below, the flame at a distance of, say, 5cm. This is the case whether the Bunsen burner be insulated or not, and it is equally true of a candle flame. A red-hot piece of iron or copper discharges a rubbed rod that is held very near it, whether above, below, or at the side. If the rubbed rod be a very thick one—say of 3cm. diameter—it is not at once discharged on the side remote from the flame. If held at a distance of, say, 8cm. from the flame, a rubbed rod of 8 or 10mm. in diameter is less rapidly discharged than at the nearer distance, but is still discharged in a few seconds; but the rate of discharge diminishes very rapidly as the distance from the flame is increased.

If a plate of metal, insulated or uninsulated, or a piece of wire gauze of even coarse texture, be held with one side close to the flame and then a charged rod be brought up to the other side of the plate, no discharge takes place. A plate of glass or ebonite held in the same way between the flame and the rod equally prevents discharge. But when the charged rod and glass plate are withdrawn together from the neighbourhood of the flame, then the glass plate is found to be charged on the side nearest the flame with a charge of opposite sign to that of the charge on the rod.

The above experimental facts, which will be more or less familiar to physicists, are here cited in order that the significance may be perceived of the experiment that will next be described. Being under the impression, which I fancy is pretty general, that the flame and the surrounding air constituted a sort of conductor which removed the charge of the rod, as it were, by licking its surface, or, perhaps, as Van Rees‡ suggested, by throwing off, under the influence of the charged rod, finite portions of itself charged inductively with the opposite electrification, I made the experiment of surrounding the rod by a strong blast of air from a foot blow-pipe, expecting thereby to prevent the discharge by blowing away the conductive air before it reached the surface of the rod; but I found that the interposed blast of air, however violent, was quite without influence on the discharge, which took place across it with perfect facility when the flame was approached. It should be mentioned that the blast alone without the flame was quite incompetent to discharge the rod.

This observation makes it, I think, quite clear that the discharge is effected, not by the flame or mass of air round it acting as a whole, but by a molecular action, the velocity of propagation of which is very great compared with the velocity of the air in the blast. All the phenomena above mentioned, and others to which I shall shortly allude, appear to be explainable as follows, and, so far as I can see, in no other way. The

* Appendix to the Fourth Report of the British Association Committee on Electrolysis, presented at the Newcastle Meeting, September, 1889.

† An historical *résumé* of early observations on the electrical properties of flames is given in the Paper of Peter Riess, "Ueber die Elektrischen Eigenschaften brennender Körper, *Pogg. Ann.*, Vol. LXI., 1884.

Digitized by Google

flame contains a large number of dissociated atoms, each with positive or negative atomic charges. A charged body, such as the rod, attracts towards itself those of opposite sign and repels those of the same sign, and under this directive influence an electrolytic action is propagated across the intervening air, the discharge being effected by the liberation of free atoms on the surface of the body. When a glass or ebonite plate is interposed this liberation takes place on the surface nearest the flame, and the plate is thereby charged. The shortness of the mean free path of molecules, and presumably also of atoms in the air at atmospheric pressure, and the incompetence, so far as I can observe, of even the most violent interposed blast of air to affect the discharge, seems to preclude the supposition that the free atoms which reach the rod are those which were originally present in the flame.

The flow in the opposite direction of atoms bearing charges of the same sign as that of the rod was put in evidence by the experiment of placing a glass or ebonite plate near to an insulated flame, and then bringing up a charged rod to the opposite side of the flame, when the plate was found to receive a charge of the same sign as that of the rod. Care must be taken to withdraw the plate as the rod is approached, otherwise it also will be discharged. A variation of this experiment is to make the like charge flow on to and charge an electroscope by means of an interposed insulated flame. For some experiments of this kind a metallic conductor connected with an electrical machine by which the charge may be maintained was found more convenient than the charged rod.

When a charged insulated body is discharged by the proximity of an insulated flame, it is not at once obvious how the equal and opposite charge on the walls of the room in which the experiment is made has been neutralised. I imagine that this must be effected by an electrolytic discharge through the air between the flame and the walls, originating in the excess of atoms charged similarly to the body, which are left over when the charge on the body is neutralised, and on which the lines of force proceeding inwards from the walls of the room now terminate. Thus the discharge involves the shifting of the ends of these lines of force from the original rigid body on to atoms which are free to move under the directive stress.

If this explanation of the discharge by a flame is correct, it should follow that discharge should be facilitated whenever free atoms are present, and I found on trial that when a rubbed ebonite rod was placed transversely in the path of the spark discharge, between the terminals of a Wimshurst machine, it lost a large amount of its charge at the passage of each spark, and was soon completely discharged. This appears to be a special instance of the phenomenon brought into notice by Dr. Schuster of a small electromotive force producing a current when the electrolyte has been broken down by a greater electromotive force.

For investigation of the temperature at which a piece of hot metal begins to act like a flame in producing discharge, a storage cell was insulated and connected with an electroscope, and charged statically; the terminals were then joined by a strip of thin platinum foil, whose length could be varied at will by means of insulating handles. The strip when shortened became more and more heated by the increased current, but only when a red heat was reached did I observe that the statical charge of the cell began to escape. This would seem to show that (in daylight at any rate) dissociated atoms are not found at the surface of the metal at a temperature below that of a red heat. The rate of escape of charge was much increased by holding an earth-connected conductor near to the red-hot platinum. This would increase the density of charge at the surface of the platinum, and therefore the electric force at the surface, *i.e.*, the directive force on the free atoms.

By hanging side by side, in a large Bunsen flame, a sheet of copper and a sheet of platinum, which were connected outside the flame by a wire having in circuit a galvanometer of about 200 ohms resistance, a feeble current of about 2×10^{-6} amperes was obtained, the flame appearing to act as an electrolyte of very high resistance, through which the current passed from the more oxidisable copper to the less oxidisable platinum. When, however, two sheets of platinum were hung in the flame so that one just touched the outside, while the other bisected the flame, a current of about the same magnitude was obtained, and in either direction at will, according to the relative positions of the plates in the flames, and the observation of Messrs. Elster and Geitel was confirmed, that the outer mantle of the flame is at a higher potential than the interior of the flame. The effect of this seemed to over-ride and obscure any effect due to the difference of the material of the two plates. I have not been able to obtain any more direct experimental evidence that there is an excess of positive atoms on the outside, and of negative on the inside of the flame.

The only experiment mentioned in this Paper that I can suppose to be new is that of the air-blast; but in the light of this, the significance of the other experiments cited seems considerably changed, and the inference that a charge of either sign, indistinguishable from the charges that are produced by friction, may be obtained on a non-conductor in air, by the liberation of free atoms on its surface, is not at present so familiar that any excuse seems required for emphasising it.

NOTE.—Professor Poynting has suggested to me, since the above was written, that the charges of the dissociated atoms might be so great and their masses so small, that the acceleration communicated under the electric stress would suffice to enable the original atoms present in the flame to traverse the air-blast.

THE PASSAGE OF ELECTRICITY THROUGH GASES.*

BY ARTHUR SCHUSTER, F.R.S.

The author has during the last two years investigated the distribution of potential in the neighbourhood of the negative pole of a discharge of electricity through rarefied gases. Knowing the rate of fall of potential, it can be determined whether there is any bodily electrification in any part of the negative glow. It was found that the negative pole is surrounded by an atmosphere of positively electrified gaseous particles extending to the outer edge of the so-called dark space. According to the author's views, this atmosphere corresponds to the polarised layer adjoining the negative electrode in an electrolyte. The cause of the sudden difference in luminosity between the dark space and the negative glow has also been investigated, and it has been found that the negative particles projected from the negative electrode pass unhindered through the dark space, while their velocity is quickly reduced in the glow proper, the translatory energy being thus changed into energy of vibration. Assuming that each particle carries the same amount of electricity as in an electrolyte, the velocity of the ions has been calculated from the behaviour of the discharge in the magnetic field. All details regarding the experiments will shortly be communicated to the Royal Society.

TRANSFORMERS.†

BY HARRIS J. RYAN.

It was with a view of obtaining so far as possible a clear understanding of all phenomena that take place in the commercial transformer, that the work producing the results here set forth was undertaken. It has not been possible at this time to prepare a Paper as complete as has been been desired, and we trust that in the near future we may add more data to that which is here presented. At the outset it should be said that the results of the experiments that are here presented were wrought out jointly by Mr. Ernest Merritt, of the Department of Physics, Cornell University, and the writer. What we had in mind in the work was an accurate determination of the exact performance of the commercial transformer whereby one should be able to derive results and data that should enable all phases of the performances of transformers to be understood clearly, and that should show the requisite principle of proper design.

It may be well to state briefly the general method we employed. A single ten-light transformer that had been made and

* Paper read before the British Association, in Section A, Newcastle-on-Tyne, September, 1889.

† A Paper read before the American Institute of Electrical Engineers, New York, December 17, 1889.

Digitized by Google

supplied for commercial purposes for incandescent lighting with 1,000 volts in the primary and 50 volts in the secondary was selected as a sample for investigation. It probably represented fairly well the average commercial performance of transformers, and might therefore be said to embody, to a certain extent at least, proportions that have proven by experience and experiment to be best for the particular purpose for which it is supplied. This transformer was operated under the same impressed E.M.F. supplied from the electric lighting plant in which it had been used for supplying incandescent lamps commercially. It was operated with its secondary open and the same closed through one lamp, five lamps, and ten lamps, and under these several conditions the exact instantaneous values of the ever-varying, primary-impressed E.M.F., primary current, and the E.M.F. at the terminals of the secondary, were observed. Again, under these several conditions the square roots of the mean squares of the above values and of the secondary current were also observed. Then with these observations, the dimensions, and the details of the construction of the transformer, many of the facts and performances that the engineer is concerned with are brought to light.

Naturally the first thing to be considered is the electrical measurements and how they were made. A point on the armature of an alternator always passes a fixed point in its circumference at a time corresponding to a definite value of the varying E.M.F. and current, alike, with regard to these quantities in the primary feeders, transformer, primary or secondary, &c., so long as the conditions remain constant. In our experiments we were only concerned with the values of the E.M.F. impressed at the terminals of the primary, the primary current, and the secondary E M.F. ; then, by changing the position of the fixed point relative to the machine, the rotating point of reference in the armature would pass the new position of the fixed point at correspondingly different values for the primary E.M.F., primary current, and secondary E.M.F., with respect to themselves and the position of the armature.

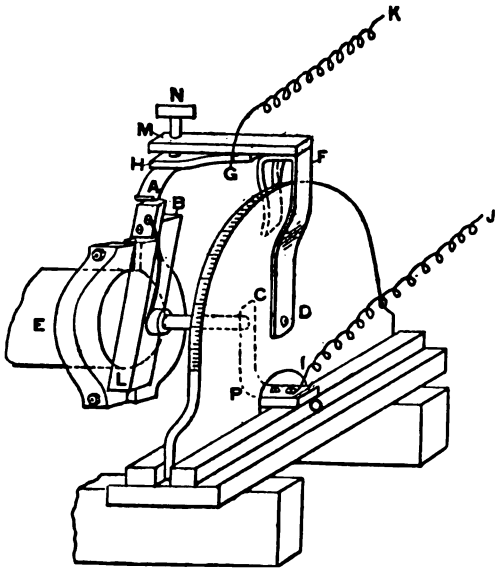

FIG. 1

In Fig. 1, B L is a prism of hard rubber bearing a projecting strip of brass, B, that, on its upper side, is filed to a dull edge. This edge is taken as a fixed point on the armature. An arm, F D, is arranged to rotate about D as a centre, a point that is in line with the axis of rotation of the armature. A semi-circular board of hard wood, attached rigidly to the dynamo frame, serves both as a support for this arm and a circumferential scale whereby the position of the arm may be observed relatively to the machine. The arm is made of brass, and given the form shown in the figure. It was bent into a U-shape at the top so as to pinch the board, and thus remained fixed in any position desired. At the top of this arm is mounted a bar of hard rubber projecting toward the dynamo parallel to the armature axis. On its underside, fastened at G, is a brass strip ; a tongue, H A, of spring brass is attached at the end, and at right angles to the brass strip H G, as shown. The position of this part of the apparatus is carefully adjusted, so that the point about which the arm rotates is in line with the axis of rotation of the armature, and the sharply upward curved end of the tongue H A, just over the edge of the brass strip at B. Then when the armature is rotated the strip H G may be sprung inward radially by turning the thumb screw N until the tip of the tongue A is heard to just lightly touch the edge at B as it passes. The arm may then be adjusted by hand so that the tongue will touch the fixed edge on the armature at any desired phase of the primary E.M.F., primary current, or secondary E.M.F. and current. Coaxially with the armature a small brass rod is mounted on the bar of hard rubber, B L. It is connected metallically to B by means of a wire. At O on the frame work supporting the semi-circular board, &c., is mounted another piece of hard rubber, insulating and supporting the thin metallic strip P C that bears against the above brass rod. G and I then are the terminals of this commutating apparatus.

In Fig. 2, E F is a non-inductive resistance in series with the primary of the transformer which is at work. At A is the apparatus described in Fig. 1, and E is an electrometer reading through a wide range.

The terminals of the above non-inductive resistance and those of the electrometer are connected together through the commutating apparatus at A. Then it must be evident that the electrometer will become charged with a difference of potential equal to that existing between the terminals of the non-inductive resistance at the instant that the fixed edge on the armature passes the tip of the tongue in the apparatus at A. By reading the indications of the electrometer, therefore, and knowing the value of the non-inductive resistance E F, the value of the primary current corresponding to the particular phase due to the position of the arm in the apparatus at A becomes known. In a similar manner the primary and secondary E.M.F. are observed by changing the connections accordingly at G_1, G_2, G_3, G_4. Then the arm is rotated to another position, corresponding to a different phase, and the corresponding values of E.M.F. and current again observed as before. In this manner we proceed at different intervals, sufficiently near, so that a curve may be determined by the values thus observed at the several intervals, so that the values of the E.M.F.s or currents, shall be accurately known at all times throughout a complete period.

A few words with regard to the electrometer at E are not out of place here. It is the form that the writer devised especially for this and similar purposes. The essential features for an electrometer for these purposes are that it shall have the widest possible range through which it will read with accuracy. Its indications must be unvaried by the absolute potential to which it is subjected as a whole. Its law must be perfectly definite, and it is also

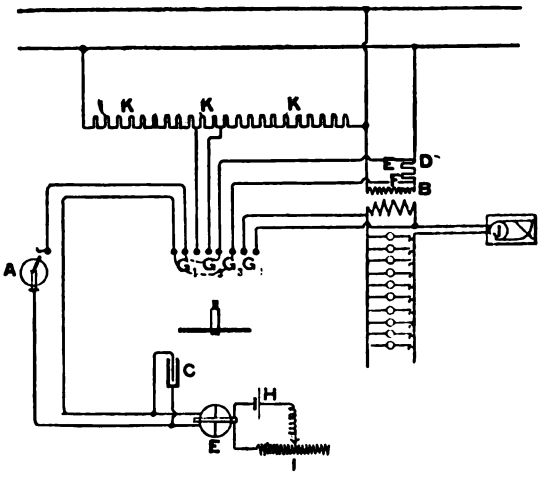

FIG. 2.

desirable that its constant be unchanging. This instrument consists essentially of cylindrical electrometer needle and quadrants. To the upper side of the electrometer needle is attached a magnetised steel mirror that acts as a magnet and as a mirror for observing the position of the same. The needle is hung by a single silk fibre from a hook in the top of the case. Metallic contact from the needle to the case is made by means of a platinum wire ·0002in. in diameter. This wire is readily provided in the desired form by using the platinum-cored silver wire that is supplied by makers of surveying apparatus. It is cut to the desired length, and hooks bent into shape at its terminals. By immersing all of it but the hooked terminals in nitric acid, the silver is dissolved away, leaving the fine platinum core terminated by the two silver hooks. One end of this platinum wire thus prepared is linked into a hook into the top of the electrometer case, and the other end into a small ring formed by a twist of the aluminum wire that surrounds the mirror. The electrometer case is circular, and the above needle and quadrants are arranged so that the magnetised mirror is at the centre of the case and the needle and quadrants below it. About the case is wound a coil of rather fine insulated copper wire. The magnetised mirror and thin coil then, when the latter is in the magnetic meridian, constitute an arrangement similar to that of a tangent galvanometer. In the electrometer, the needle, case, and one set of quadrants are connected together, and form one terminal,

Digitized by Google

and the other set of quadrants, being connected together, form the other terminal of the instrument, in the manner set forth in the diagram. Thus, then, when the electrometer terminals are subjected to a difference of potential, the needle is acted upon by a couple brought about by the electrostatic forces, and is deflected from its position of equilibrium. Current from a gravity cell in circuit with a suitable rheostat is sent through the coil on the electrometer in such a direction that the needle is brought towards its zero position by the action of the coil carrying the current on the magnetised mirror. The current is then further adjusted till the needle stands balanced at zero under the mutual action of the electrostatic and the electro-magnetic forces. Under such circumstances, then, the difference of potential is proportional to the square root of the current.

If we can, as was the case when the measurements here presented were made, consider the E.M.F. of our cell constant, the difference of potential is likewise proportional to the square root of the reciprocal of the total resistance in circuit with the cell. Parallel readings, taken with a standard voltmeter throughout a range varying from 3 to 600 volts, gave identical results, showing no deviation from the above law, and an unvarying constant. On account of the metallic case and its connection to the rest of the apparatus, the indications of the electrometer are, so far as could be observed, entirely independent of the absolute potential to which it is subjected as a whole. In Fig. 2, when contact was made at A, and the electrometer charged to the potential difference to which its terminals were then subjected, it was found that considerable of the charge was dissipated by leakage during the course of a revolution of the armature, no matter how good the insulation of the apparatus was. A one-half microfarad mica condenser was then placed in multiple arc with the terminals of the electrometer at C. Then, after a few revolutions of the armature, the condenser became charged to precisely the same difference of potential existing at the terminals of the electrometer D B, as shown in Fig. 2, when the rotating edge on the armature passed the tip of the tongue on the arm at A. Under these circumstances the leakage that occurred was entirely unobservable as compared with the charge in the condenser during the course of time required for the armature to make many revolutions. Thus arranged, then, the electrometer would give accurate readings of the primary and secondary E.M.F.s, and primary current corresponding to the connection of the terminals and the position of the arm A. Again, the square root of the mean square of any of these values could at any time be read from the electrometer by short-circuiting the apparatus at A, and cutting out the condenser at C. For the purpose of obtaining the curve of impressed E.M.F. and the $\sqrt{\text{mean}^2}$ of the same, 22 50-volt lamps were put in series across the primary circuit. The $\sqrt{\text{mean}^2}$ of the impressed E.M.F. in the primary was then obtained by reading by means of the electrometer with the condenser cut out and the commutating apparatus short-circuited, the $\sqrt{\text{mean}^2}$ difference of potential existing between each set of two lamps. In this way 11 readings were obtained, the sum of which was the total impressed E.M.F. This served as a calibration of the non-inductive resistance formed by the lamps. At the same time that these observations were made, two lamps were determined upon to be used in all subsequent observations on the total E.M.F. The above observations served, then, as a calibration for the indications of the two lamps thus to be used. For the constant obtained by the ratio of the above total E.M.F., to the E.M.F. of these lamps taken at the same time, always served to deduce the total $\sqrt{\text{mean}^2}$, or any particular value corresponding to a particular phase of the impressed primary E.M.F. when the same had been observed with regard to the two lamps in the group thus set apart. In this way we avoided the direct measurements of the total impressed E.M.F. Two 50-volt lamps, E and F, wereplaced in series with the primary as a non-inductive resistance, and, as previously stated, the $\sqrt{\text{mean}^2}$, and the values corresponding to any particular phase of the fall of potential through these lamps, were observed. This gave a measure of the $\sqrt{\text{mean}^2}$, or any particular value corresponding to a particular phase of the primary current, when the resistance of these lamps was known at the temperature to which they were brought by the current. A curve of resistance corresponding to the range of currents through which we used these lamps was determined carefully by Mr. Merritt at the Cornell Magnetic Observatory. In series with the secondary circuit was placed a gravity ammeter containing a few small turns, and correct in its adjustment. It indicated the $\sqrt{\text{mean}^2}$ in the same way that an electro-dynamometer would have done. The observing of the various values of the secondary E.M.F. required no special arrangement: this was done direct in all cases. Since the secondary was always at work on a circuit possessing almost no inductance, no determinations of the curve of secondary circuits were made, for it would be found to be so nearly in unison with the secondary E.M.F., and possees all the characteristic variations of the same. The $\sqrt{\text{mean}^2}$ of its value was always known from the indications of the ammeter. As a load for the transformer, 10 16 candle-power 50-volt lamps were provided that could be turned on and off as desired, and they were at an average distance from the transformers of not more than 5ft.

G_1, G_2, G_3, G_4 represent, in Fig. 2, the various terminals conveniently arranged on a switch-board for ready adjustment for any desired set of connections. The adjustable resistance at I consisted of a plug resistance box enabling one to get any number of ohms in circuit from 100,000 down. It was very conveniently arranged, but a suitable slide rheostat and a damped magnet on the electrometer needle would have facilitated greatly the rapidity with which observations could be taken. The mode of procedure was to set the brush at some suitable point of starting out; then, corresponding to this point, readings of the instantaneous values of the primary E.M.F. were made. When lamps were turned on in the secondary, the ammeter in that circuit was also read. The brush was then moved forward to a new position, and the above readings repeated. This was continued until we had gone over a complete period of two alternations; then the $\sqrt{\text{mean}^2}$ readings of the primary and secondary E.M.F.s and primary current were made. To do this required a period of time covering usually not more than two and a-half hours. Careful observations were made which showed that the insertion of one, two, or three lamps in the primary circuit *did not perceptibly change the relation* of the primary E.M.F. and current and secondary E.M.F. The indications of the ammeter gave data for correcting for variations of the speed of the dynamo, which throughout were not great.

The following data should be given with regard to the transformer that was used by us:—

No. of turns in the primary circuit coil	675
No. of turns in the secondary coil.....	35
Resistance of the primary	21·8 ohms.
Resistance of the secondary	·04 ohms.

The iron discs of the magnetic circuit of the transformer were made ½ millimetre in thickness, and its surface merely oxidised so that no special insulating material was provided between the laminations. The total volume of laminated iron used in the transformer was 2,050 cubic centimetres. The mean cross-section of the magnetic circuit was 63·3 square centimetres, and the mean length of the magnetic circuit 30·8 centimetres.

(To be continued.)

MEETINGS OF SCIENTIFIC SOCIETIES, &c.

(To night) FRIDAY, January 10th.

INSTITUTION OF CIVIL ENGINEERS.

7.30 p.m. Students' Meeting. Paper to be read, "The Irrigation Works on the Cauvery Delta." By ALFRED CHATTERTON, B.Sc.

MONDAY, January 13th.

LONDON INSTITUTION.

5 p.m. Lecture: "University Education in London." By Sir PHILIP MAGNUS, B.Sc., B.A.

TUESDAY, January 14th.

ROYAL VICTORIA HALL.

8:30 p.m. Lecture: "The Bottom of the Sea." By D. P. H. CARPENTER.

INSTITUTION OF CIVIL ENGINEERS.

8 p.m. Ordinary Meeting. Paper to be read, "Recent Dock Extensions at Liverpool." By GEORGE FOSBERY LYSTER, M.I.C.E.

WEDNESDAY, January 15th.

SOCIETY OF ARTS.

8 p.m. Ordinary Meeting. Adjourned discussion on SIR ROBERT RAWLINSON'S Paper on "London Sewerage and Sewage."

THURSDAY, January 16th.

LONDON INSTITUTION.

6 p.m. Lecture: "The Sugar Islands of the West." By D. MORRIS, M.A.

FRIDAY, January 17th.

SOCIETY OF ARTS.

5 p.m. Indian Section. "The India Office Records." By F. C. DANVERS.

*** Particulars of meetings to be held or Papers to be read before Scientific Societies during the ensuing week should reach us not later than Thursday, 6 p.m.

The Electrician.

Published every Friday. Price Fourpence; Post Free, Fourpence Halfpenny
Editorial, Publishing and Printing Offices:

No. 1, SALISBURY COURT, FLEET STREET, LONDON, E.C.

Telephone No. 2714. *Telegrams:* "ELECTRICIAN NEWSPAPER, LONDON."

All Communications to be addressed to "THE ELECTRICIAN," *1, Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to* "THE ELECTRICIAN."

All letters intended for insertion in "THE ELECTRICIAN," *or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

"THE ELECTRICIAN" *is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.*

"THE ELECTRICIAN" *is on sale at the railway bookstalls throughout the United Kingdom on Friday morning, and can be obtained of all Booksellers and Newsvendors; or direct from the Publishing Offices as above.*

SPECIAL NOTICE.

Owing to the increase in the number of pages of "THE ELECTRICIAN," in order to partly cover the increased postage, we have been compelled to revise the rates for Foreign Subscriptions, which are now as follows:—

	3 months.	6 months.	12 months
For Foreign Parts and Colonies:—	s. d.	s. d.	s. d.
Within Postal Union	6 6	12 6	24 0
Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7 6	14 6	28 0
The rates for the United Kingdom remain as follows:—	5 0	10 0	19 6

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to the office.

TRADE ADVERTISEMENTS *intended for the current issue must be handed in not later than First Post on Thursday morning.*

SMALL PREPAID ADVERTISEMENTS *(for Rates see page xiii.) are accepted up to 4:30 p.m. on Thursday.*

TECHNICAL PRINTING.

"THE ELECTRICIAN" PRINTING AND PUBLISHING COMPANY (LIMITED) *beg to inform Electricians, Electric Light Engineers, &c., that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

"THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK.

Royal 8vo.

Early in each year is issued "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1889 Edition consisted of more than 600 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with popularly-written Biographical Notices of the leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

The issue for 1890, which will be still further enlarged and improved, is in active preparation. New Names and Addresses, Corrections, Advertisements, &c., should be forwarded at once to the Publishing Office, **1,** *Salisbury-court, Fleet-street, London, E.C.*

OUR SUPPLEMENT.

With this Issue of "The Electrician" is published a Steel Plate Portrait of Dr. JOHN HOPKINSON, the newly-elected President of the Institution of Electrical Engineers.

A limited number of copies have been mounted on India Paper, and for these early application must be made. Price 1s.; post free, on roller, 1s. 2d.

The Portrait, in a neat frame, will be supplied at 4s. 6d., post free, 5s. If mounted, 5s. 6d., post free, 6s.

"THE ELECTRICAL WORLD" OF NEW YORK.

"THE ELECTRICAL WORLD" OF NEW YORK *can be obtained from* "THE ELECTRICIAN" *Office, Salisbury-court, Fleet-street, London, E.C. The Rate of Subscription (payable in advance), is* **£1 1s.** *per annum. Single Copies* **price 6d. each; post free, 8d.**

1889.

Continuing this week our review of the work done during the past twelve months, we append a few more reports from the leading electrical firms. Early in the year 1889 the business of Messrs. Laing, Wharton, and Down was divided, and that portion of it which related more especially to the establishment of central stations, and the exploitation of the Thomson-Houston systems of electric lighting generally, became the particular care of the Laing, Wharton and Down Construction Syndicate (Limited). The following, amongst others, have been the installations carried out by the Syndicate, viz., extension at St. Pancras terminus of the Midland Railway, Deptford Central Station, Bradford Station (Midland Railway), the Railway Clearing House, Central Station plants at Exeter, Bath, and Weybridge, and extensions at Taunton, Waterford, and Reading, whilst successful temporary work has been done at the Birmingham Exhibition (for which a special gold medal was awarded), and the sea front at Portsmouth for the Naval Review. No better evidence can be given of the great increase in the operations of the firm than that their staff has been trebled within the year. An important feature of the business has been the acquirement of the European agency for okonite insulated wires and cables, which

Digitized by Google

obtained a gold medal at the Paris Exhibition. Nothing but time alone can fully substantiate the claims made for this material, but past experience in the United States leads to the belief that it will at least prove quite equal to the best of its competitors. The following are some of the more important installations carried out by Messrs. B. Verity and Sons during the year:—The Savoy Hotel, the largest private plant in the world; Sir John Pender's, at Foot's Cray; the Grand Hotel, Brighton; Exeter Hall, Strand; the City Liberal Club; Messrs. Coutts' Bank; the new Theatre Royal and several hotels and private houses at Exeter; several houses at Bath, and half-a-dozen Atlantic steamers. Some idea of the amount of work done by this firm may be gathered from the fact that during the last eleven months they have used on their own works over 24,000 incandescent lamps in some 110 separate installations, an average of over two installations per week. With regard to future business, this firm has several heavy contracts in hand, and are now engaged in erecting the machinery for the electric light at Mr. D'Oyly Carte's new theatre in Charing Cross-road, where the total capacity of the plant will be nearly three thousand lights. In addition to several large installations in the country, they are now erecting the machinery for an important installation at Buenos Ayres, and are carrying the entire work through, including the wiring both for electric lighting and electric bells, and the fittings, the latter being of the most elaborate character. The General Electric Company have during the year increased both their manufacturing premises as well as their warehouses and offices. The factory in Manchester now gives employment to over 300 men, the machinery throughout being of the latest type. In London, besides the increased sale of their standard articles, the demand for specialities, such as Dr. Aron's meters, Apostle carbons, &c., has been very great. The Manchester Edison-Swan Company have been very fully employed during 1889. In the early part of the year they completed a central station on the low-tension system at St. John's, Newfoundland, the Houses of Assembly, the Government House, and other buildings being lighted; they have also carried out numerous private installations, many of which were of large size. A tolerably accurate estimate of the spread of electric lighting in this district may be formed from the fact that during the past year this Company have supplied 40,000 incandescent lamps.

The Callender's Bitumen Company report that their work during 1889 has been very largely in connection with underground mains for electric lighting, the Company having carried out several large contracts, undertaking the excavation and all the operations consequent thereon, the construction of the protecting conduit, and the manufacture and laying complete of the cables themselves, with all service and other boxes, to form a complete distributing network. The most important of these contracts was at Liverpool, where they have laid a complete network throughout nearly the whole of the business quarter of the city for the Liverpool Electric Supply Company. Similar work has also been done for the Metropolitan Electric Supply Company, Messrs. A. and S. Gatti, the Chelsea Electricity Supply Company, and at Bath. This Company has also supplied the cables for central station work at Lynmouth and Lynton, Gothenburg (Sweden), La Plata, Ensenada, Rosario, Buenos Ayres, and has been very busy supplying cables for the navy. The Telegraph Manufacturing Company report that the year has been an extremely busy one, especially the last six months, during which the output has been doubled, all departments having been fully occupied. The Phosphor Bronze Company report extensions of works and large orders.

Messrs. Willans and Robinson report that the work of the year, though of course greatly hampered by the destruction of the Company's machine shops by fire in November, 1888, has nevertheless much exceeded that of any previous year. Electric light work, by its importance and urgency, has claimed the greater part of the Company's attention, and the fact that the electric light engines made by this one firm (or put in hand for completion within a few weeks from now) are capable of indicating about *eighteen thousand horse-power*, shows not only how great a reputation the Willans engine and its system of direct-driving have obtained, but what a large amount of lighting work is now in progress in the country. Out of the 18,000 horse-power, about 4,000 is for ship lighting, but the balance is nearly all for land installations in England. Central stations, of course, account for the greater part of the work. Amongst the large customers in the year may be mentioned the English Admiralty, for whom at least sixty engines, mostly of large size, have been put in hand. In nearly all the large installations the engines and dynamos are divided into units of about 200 I.H.P., this appearing to be very convenient in practice, and corresponding with the standard H. size of the Willans engine. One or two engines of G.C. size (80 I.H.P. each) are usually included, so as to make it unnecessary to use the large engines with only a light load. Reports are beginning to come in of the coal consumption at various stations, and the results shown are of the most satisfactory kind, so that it may be considered doubtful, at least for the present, whether any advance beyond the 200 I.H.P. size is called for. Messrs. Willans and Robinson are, however, prepared to build engines indicating 550 I.H.P., at 280 revolutions per minute, should heavy central station work give rise to any such demand.

The year 1889 has not produced anything very novel in dynamos. The process of settling down with regard to designs which has been noticeable for the last two or three years has continued, and there may be said to be almost a complete weeding out of forms of machines that presented peculiar features. In direct-current machines drum armatures have to a certain extent replaced armatures with "Gramme" windings, and the field-magnets have shown a disposition to become more and more of the simple single horseshoe type, although it has been found that this type is somewhat heavier than that with double horseshoes or consequent poles. For some purposes the ring winding will no doubt always be adhered to. It is usually much easier to repair a faulty coil in such an armature than in the case of a drum winding, but this does not apply where the drum winding has the single conductor form. It is to be noted, however, that while the use of the simple drum machine has been increasing in this country, the movement on the Continent, and especially in Germany, has been, for large sizes of machines, in the direction of multipolar ring machines. English electrical engineers must not lose sight of this fact, for on the Continent direct-current dynamos have had to be made for much larger output than in England, and the difficulties experienced with simple two-pole machines of large size have been sufficient to show that such machines are not always the most suitable. There have been rumours of trials made with disc machines having some arrangement of radial conductors moving between poles of opposite sign, and without iron cores in the armatures. Mr. Crompton, for instance, is understood to be experimenting with the "Fritsche" dynamo, which is of this type, and which in its original form had iron armature conductors. But it remains to be seen whether this will give good results. The problem of making such machines practicable has always attracted the attention of electricians, but so far without any very good results. In direct-current motors the same process of settling down which we have observed with regard to dynamo has taken place, as of course follows from the fact that mos makers now recognise that the distinctions in form and propor-

Digitized by Google

tions between motors and dynamos are of a very trifling character. In very small motors there is no development to chronicle. Very few such moters are made or called for in this country, but probably the extension of central station working will soon produce a demand.

Turning to alternate currents, we find little change in the apparatus, but a considerable improvement in the state of knowledge. At the end of last year there appeared to be a growing belief that the alternate-current machines of the future would in some way or other resemble direct-current drum machines so far as the armatures were concerned, and that the older type of disc armature was in process of disappearing. It has, however, been recognised in the course of the year that machines are better without iron in the armatures, and the structural difficulties which were supposed to render the use of iron necessary do not appear to have been encountered by Ferranti and Mordey, while the losses incidental to its use have been avoided by those designers. We look with interest to the year just started to find whether the tendency to displace iron is confirmed. We think that the last twelve months have also revealed the fact that for the large alternate-current distribution schemes now being undertaken it will be quite possible to use machines of moderate size instead of very large machines.

It was expected that 1889 would see the Deptford Works of the London Electric Supply Corporation in actual operation; but for this we must wait a little longer. On the successful completion and operation of this station very much more depends than the well-being of the company directly concerned. It is not too much to say, however, that many experienced and competent electrical engineers regard the Deptford scheme with very considerable anxiety. Its failure, or comparative failure, by weakening public confidence, would give a blow to the industry from which recovery would be slow, while its success would fully confirm the improved feeling with which schemes for electric lighting are now regarded. All who have the true interests of the industry at heart will wish Mr. Ferranti well out of any difficulties which may have arisen in connection with his gigantic scheme. With regard to alternate-current motors, progress is very slow, partly, no doubt, because the real demand for them has not become urgent. With the establishment of numerous central stations, however, we hope to see motors of this class largely in use. The principle of working, which has been termed the "reaction principle," and which was worked out almost simultaneously by Ferraris, Tesla, and Elihu Thomson, does not appear to have yet fully justified the expectations that were at one time formed with regard to it, and in this country, at any rate, we have seen no applications of the principle for actual motors, although it is in use for meters.

In the cable world there is but little to chronicle. In the early part of the year the Eastern Telegraph Company laid a cable 52 miles in length, from the Island of Perim to Obock, the French Government subsidising the undertaking. The Eastern Extension, Australasia, and China Telegraph Company have during the current year laid the new cable between Banjoewangie (Java) and Roebuck Bay (Western Australia), a length of 890 knots, and they have renewed the Saigon-Hongkong section to the extent of 260 miles. At home the transfer of the Anglo-Continental cables to the respective Governments, and the practical extinction of the old Submarine Telegraph Company, took place early in the year. Greater facilities and improved working have been gradually introduced, with the result that a large increase of traffic has accrued.

The great event of 1889, so far as the telephone is concerned, is, of course, the amalgamation in May last of the three leading companies, an amalgamation which has not so far resulted in the improvements and extensions which we were confidently assured would inevitably flow from the union of the United, National, and Lancashire and Cheshire Companies. The National Telephone Company, from which particulars have been obtained down to November 27, 1889, was working no fewer than 251 exchanges and 475 call offices. Its exchange lines numbered 21,011 and its private lines 4,702. The fact that nearly 200 of the company's centres are in telephonic connection is a remarkable testimony to its energy and enterprise. The South of England Telephone Company, which still remains outside the northern combination, now possesses 1,780 miles of wire, and has during the past year opened seven additional exchanges, making a total of 31. Its exchange subscribers have increased from 1,758 to 2,206, and its private wire renters from 465 to 549. The messages transmitted through the exchanges in November, 1888, averaged 9,900 per day: in the corresponding month of 1889 this number had increased to 12,600. Several trunk lines have been run, connecting up various local exchanges. The accounts published in June last showed an increase of £4,000 in the year's revenue compared with the previous year's report. The Western Counties and South Wales Telephone Company has now 39 exchanges, and had a total of 2,343 subscribers and trunk renters on December 14, 1889. The principal exchanges are—Bristol, with 451 subscribers; Plymouth, with 278; Bournemouth, 228; Portsmouth, 194; Torquay, 126; and Southampton, 105. On December 14, 1889, this company had 669 private lines distributed over 130 places in the company's territory, thus in many cases bringing the telephone into the most remote towns and villages, and for the greatest variety of purposes, from the farm and rural requirements of one part of the country to the mines and collieries of another. In the Bristol, Bath, Gloucester, and South Wales district, the most distant points connected by trunk lines are Bath to Llanelly, 142½ miles; and in Devonshire the most distant points are Plymouth to Dartmouth, 36 miles. In the South of England Bournemouth is connected with Poole, and Portsmouth with Southampton and Winchester. The trunks between Portsmouth and Bournemouth are almost completed. The most distant point will then be Poole to Portsmouth—58 miles. In all, the company have 373 miles of trunk routes already completed. The calls on these trunk lines for the month of November, 1889, were 18,157. In January a span of wire 800 yards in length was erected over the River Dart at a height of 288ft. above high-water mark. Silicium bronze wire, No. 17, was used, weighing 24lb. for the span. This span is believed to be the longest in England. The working has been perfect, notwithstanding two heavy gales which have occurred since its erection. The total wire mileage of the Northern District Company now amounts to 3,019, and its subscribers number 1,090. It is proposed shortly to extend lines from Newcastle to Hexham, Carlisle, and Morpeth; Durham to Stockton; Blyth to Alnwick; Alnwick to Berwick; Darlington to Northallerton. The last-named connection will give communication with the whole of the National Telephone Company's English system. During the year this company's exchange subscribers have increased by 315, and it is anticipated that a continued increase will take place as existing Post Office agreements expire. The number of calls has increased from 891,517 in 1888 to 1,723,184 in 1889.

The telephone record for the year 1889 has, it will thus be seen, been one of steady progress. When the time comes for a review of the achievements of 1890, we hope to be able to record that telephonic communication has been successfully established between London and Paris, a proposition which, we believe, is under the consideration of the Post Office.

OBITUARY.

STEPHEN JOSEPH PERRY.

Father Perry, whose untimely decease whilst engaged on the Eclipse Expedition it is our sad duty to chronicle, was one of the greatest authorities on terrestrial magnetism. He was not the first Jesuit who has taken an active part in magnetic or electrical researches. Since the days of Athanasius Kircher there have been many scientific Jesuits. Father Beccaria, at the close of the last century, did much to improve our knowledge of atmospheric electricity; and the late Father Secchi, though better known for his astronomical work, was also an accomplished electrician. When the British Association met at Montreal in 1884, Father Perry was one of the first arrivals, and it is needless to say that he received a warm welcome, and gave a capital lecture.

Father Perry was born in London in 1833, and, after studying at the Catholic colleges of Douay and Rome, entered the Society of Jesus in 1853. Between this latter date and 1860 he went through a special course of mathematics at Paris, and was appointed professor and director of the observatory at Stonyhurst College in 1860. The only occasions on which he has been absent from Stonyhurst for any length of time were for studying theology at St. Beuno's College (four years) and to take part in scientific expeditions. Among these expeditions we may mention the magnetic survey of France in 1868-9, the transits of Venus in 1874 and 1882, and the eclipses of 1886, 1887, and 1889 at the West Indies, Russia, and Salut Isles. He was elected Fellow of the Royal Society in 1874, and he belonged to several other learned societies. He commanded the respect of all who were acquainted with his personal character and his scientific work by his utter self-abnegation when there was work to be done, being always ready to volunteer regardless of the intense sufferings which the expeditions cost him.

CHARLES LEVER.

It is with great regret that we announce the sudden death on Sunday last, at his father's residence, of Mr. Charles Lever so well known as the inventor of many electrical appliances. Mr. Lever was born at Gorton, near Manchester, 15th February, 1862, and was educated chiefly at Southport and Bowden. In 1878 Mr. Lever began the study of electricity and magnetism; and in 1879 made two trips to America. On his first return to this country he wrote an article on "Telephonic Exchanges," published in the *Manchester Guardian* in the early part of 1878; also an article on Mr. Edison and his inventions in the *St. James's Magazine* of August 1879. About this time Mr. Lever invented his first electric lamp, which was perfected and patented in August, 1881. He took out several patents in this country—some of which were also patented abroad—for electric light apparatus, dynamos, and telephones.

THE INSTITUTION OF ELECTRICAL ENGINEERS.

DR. JOHN HOPKINSON'S PRESIDENTIAL ADDRESS.

Magnetism.

As old as any part of electrical science is the knowledge that a needle or bar of steel which has been touched with a loadstone will point to the North. Long before the first experiments of Galvani and Volta the general properties of steel magnets had been observed—how like poles repelled each other, and unlike attracted each other; how the parts of a broken magnet were each complete magnets with a pair of poles. The general character of the earth's magnetism has long been known—that the earth behaves with regard to magnets as though it had two magnetic poles respectively near the rotative poles, and that these poles have a slow secular motion. For many years the earth's magnetism has been the subject of careful study by the most powerful minds. Gauss organised a staff of voluntary observers, and applied his unsurpassed powers of mathematical analysis to obtaining from their results all that could be learned.

The magnetism of iron ships is of so much importance in navigation that a good deal of the time of men of great power has been devoted to its study. It was *the* scientific study of Archibald Smith; and Airy and Thomson have added not a little to our practical knowledge of the disturbance of the compass by the iron of the ship. Sir W. Thomson, in addition to much valuable practical work on the compass, and experimental work on magnetism, has given the most complete and elegant mathematical theory of the subject. Of late years the development of the dynamo machine has directed attention to the magnetisation of iron from a different point of view, and a very great deal has been done by many workers to ascertain the facts regarding the magnetic properties of iron. The upshot of these many years of study by practical men interested in the mariners' compass or in dynamo machines by theoretical men interested in looking into the nature of things, is, that although we know a great many facts about magnetism, and a great deal about the relation of these facts to each other, we are as ignorant as ever we were as to any reason why the earth is a magnet, as to why its magnetic poles are in slow motion in relation to its substance, or as to why iron, nickel, and cobalt are magnetic, and nothing else, so far as we know, is to any practical extent. In most branches of science the more facts we know the more fully we recognise a continuity in virtue of which we see the same property running through all the various forms of matter. It is not so in magnetism; here the more we know the more remarkably exceptional does the property appear, the less chance does there seem to be of resolving it into anything else. It seems to me that I cannot better occupy the present occasion than by recalling your attention to, and inviting discussion of, some of those salient properties of magnetism as exhibited by iron, nickel, and cobalt—properties most of them very familiar, but properties which any theory of magnetism must reckon with and explain. We shall not touch on the great subject of the earth as a magnet—though much has been recently done, particularly by Rücker and Thorpe—but deal simply with magnetism as a property of these three bodies, and consider its natural history, and how it varies with the varying condition of the material.

To fix our ideas, let us consider, then, a ring of uniform section of any convenient area and diameter. Let us suppose this ring to be wound with copper wire, the convolutions being insulated. Over the copper wire let us suppose that a second wire is wound, also insulated, the coils of each wire being arranged as are the coils of any ordinary modern transformer. Let us suppose that the ends of the inner coil, which we will call the secondary coil, are connected to a ballistic galvanometer; and that the ends of the outer coil, called the primary, are connected, through a key for reversing the current, with a battery. If the current in the primary coil is reversed, the galvanometer needle is observed to receive a sudden or impulsive deflection, indicating that for a short time an electromotive force has been acting on the secondary coil. If the resistance of the secondary circuit is varied, the sudden deflection of the galvanometer needle varies inversely as the resistance. With constant resistance of the secondary circuit the deflection varies as the number of convolutions in the secondary circuit. If the ring upon which the coils of copper wire are wound is made of wood or glass—or, indeed, of 99 out of every 100 substances which could be proposed—we should find that for a given current in the primary coil the deflection of th galvanometer in the secondary circuit is substantially the same. The ring may be of copper, of gold, of wood, or glass—it may be solid or it may be hollow—it makes no difference in the deflection of the galvanometer. We find, further, that with the vast majority of substances the deflection of the galvanometer in the secondary circuit is proportional to the current in the primary circuit. If, however, the ring be of soft iron, we find that the conditions are enormously different. In the first place, the deflections of the galvanometer are very many times as great as if the ring were made of glass, or copper, or wood. In the second place, the deflections on the galvanometer in the secondary circuit are not proportional to the current in the primary circuit; but as the

Digitized by Google

current in the primary circuit is step by step increased, we find that the galvanometer deflections increase somewhat as is illustrated in the accompanying curve (Fig. 1), in which the abscissæ are proportional to the primary current, and the ordinates are proportional to the galvanometer deflections. You observe that as the primary current is increased the galvanometer deflection increases at first at a certain rate; as the primary current attains a certain value the rate at which the deflection increases therewith is rapidly increased, as shown in the upward turn in the curve. This rate of increase is maintained for a time, but only for a time. When the primary current attains a certain value the curve bends downward, indicating that the deflections of the galvanometer are now increasing less rapidly as the primary current is increased; if the primary current be still continually increased, the galvanometer deflections increase less and less rapidly.

Now, what I want to particularly impress upon you is the enormous difference which exists between soft iron on the one hand and ordinary substances on the other. On this diagram I have taken the galvanometer deflections to the same scale for iron, and for such substances as glass or wood. You see that the deflections in the case of glass or wood, to the same scale, are so small as to be absolutely inappreciable, whilst the deflection for iron at one point of the curve is something like 2,000 times as great as for non-magnetic substances. This extraordinary property is possessed by only two other substances besides iron—cobalt and nickel. On the same figure are curves showing on the same scale what would be the deflections for cobalt and nickel, taken from Prof. Rowlands's Paper.

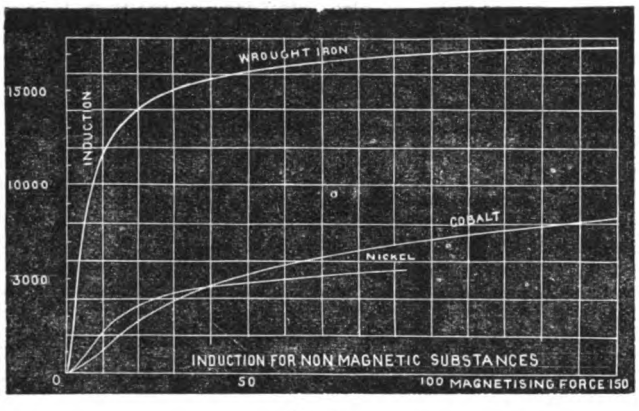

Fig. 1.

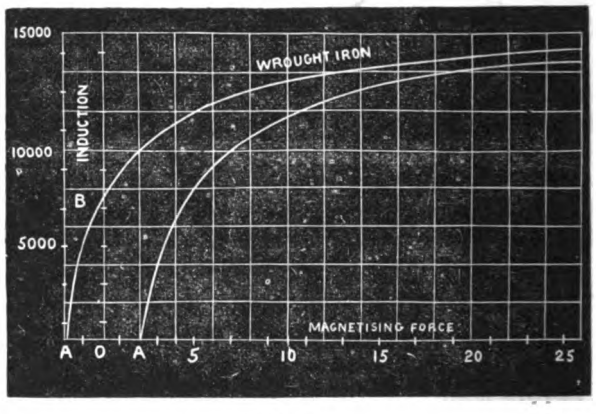

Fig. 2.

You observe that they show the same general characteristics as iron, but in a rather less degree. Still, it is obvious that these substances may be broadly classed with iron in contradistinction to the great mass of other bodies. On the other hand, diamagnetic bodies belong distinctly to the other class. If the deflection with a non-magnetic ring be unity, that with iron, as already stated, may be as much as 2,000; that with bismuth, the most powerful diamagnetic known, is 0·999825—a quantity differing very little from unity. Note, then, the first fact which any theory of magnetism has to explain is: Iron, nickel, and cobalt, all enormously magnetic; other substances practically non-magnetic. A second fact is: With most bodies the action of the primary current on the secondary circuit is strictly proportional to the primary current; with magnetic bodies it is by no means so.

You will observe that the ordinates in these curves, which are proportional to the kicks or elongations of the galvanometer, are called induction, and that the abscissæ are called magnetising force. Let us see a little more precisely what we mean by the terms, and what are the units of measurement taken. The elongation of the galvanometer measures an impulsive electromotive force—an electromotive force acting for a very short time. Charge a condenser to a known potential, and discharge it through the galvanometer: the needle of the galvanometer will swing aside through a number of divisions proportional to the quantity of electricity in the condenser—that is, to the capacity and the potential. From this we may calculate the quantity of electricity required to give a unit elongation. Multiply this by the actual resistance of the secondary circuit and we have the impulsive electromotive force in volts and seconds, which will, in the particular secondary circuit, give a unit elongation. We must multiply this by 10^8 to have it in absolute C.-G.-S. units. Now the induction is the impulsive electromotive force in absolute C.-G.-S. units divided by the number of secondary coils and by the area of section of the ring in square centimetres. The line integral of magnetising force is the current in the primary in absolute C.-G.-S. units—that is, one-tenth of the current in amperes—multiplied by 4π. The magnetising force is the line integral divided by the length of the line over which that line integral is distributed. This is, in truth, not exactly the same for all points of the section of the ring—an imperfection so far as it goes in the ring method of experiment. The absolute electro-magnetic C.-G.-S. units have been so chosen that if the ring be perfectly non-magnetic the induction is equal to the magnetising force. We may refer later to the permeability, as Sir W. Thomson calls it: it is the ratio of the induction to the magnetising force causing it, and is usually denoted by μ.

There is a further difference between the limited class of magnetic bodies and the great class which are non-magnetic. To show this, we may suppose our experiment with the ring to be varied in one or other of two or three different ways. To fix our ideas, let us suppose that the secondary coil is collected in one part of the ring, which, provided that the number of turns in the secondary is maintained the same, will make no difference in the result in the galvanometer. Let us suppose, further, that the ring is divided so that its parts may be plucked from together, and the secondary coil entirely withdrawn from the ring. If now the primary current have a certain value, and if the ring be plucked apart and the secondary coil withdrawn, we shall find that, whatever be the substance of which the ring is composed, the galvanometer deflection is one-half of what it would have been if the primary current had been reversed. I should perhaps say approximately one-half, as it is not quite strictly the case in some samples of steel, although, broadly speaking, it is one-half. This is natural enough, for the exciting cause is reduced from—let us call it a positive value, to nothing when the secondary coil is withdrawn; it is changed from a positive value to an equal and opposite negative value when the primary current is reversed. Now comes the third characteristic difference between the magnetic bodies and the non-magnetic. Suppose that, instead of plucking the ring apart when the current had a certain value, the current was raised to this value and then gradually diminished to nothing, and that then the ring was plucked apart and the secondary coil withdrawn. If the ring be non-magnetic, we find that there is no deflection of the galvanometer; but, on the other hand, if the ring be of iron we find a very large deflection, amounting, it may be, to 80 or 90 per cent. of the deflection caused by the withdrawal of the coil when the current had its full value. Whatever be the property that the passing of the primary current has imparted to the iron, it is clear that the iron retains a large part of this property after the

Digitized by Google

current has ceased. We may push the experiment a stage further. Suppose that the current in the primary is raised to a great value, and is then slowly diminished to a smaller value, and that the ring is opened and the secondary coil withdrawn. With most substances we find that the galvanometer deflection is precisely the same as if the current had been simply raised to its final value. It is not so with iron; the galvanometer deflection depends not alone upon the current at the moment of withdrawal, but on the current to which the ring has been previously subjected. We may then draw another curve (Fig. 2) representing the galvanometer deflections produced when the current has been raised to a high value and has been subsequently reduced to a value indicated by the abscissæ. This curve may be properly called a descending curve. In the case of ordinary bodies this curve is a straight line coincident with the straight line of the ascending curve, but for iron is a curve such as is represented in the drawing. You observe that this curve descends to nothing like zero when the current is reduced to zero; and that when the current is not only diminished to zero, but is reversed, the galvanometer deflection only becomes zero when the reserved current has a substantial value. This property possessed by magnetic bodies of retaining that which is impressed upon them by the primary current has been called by Prof. Ewing "hysteresis," or, as similar properties have been observed in quite other connections, "magnetic hysteresis." The name is a good one, and has been adopted. Broadly speaking, the

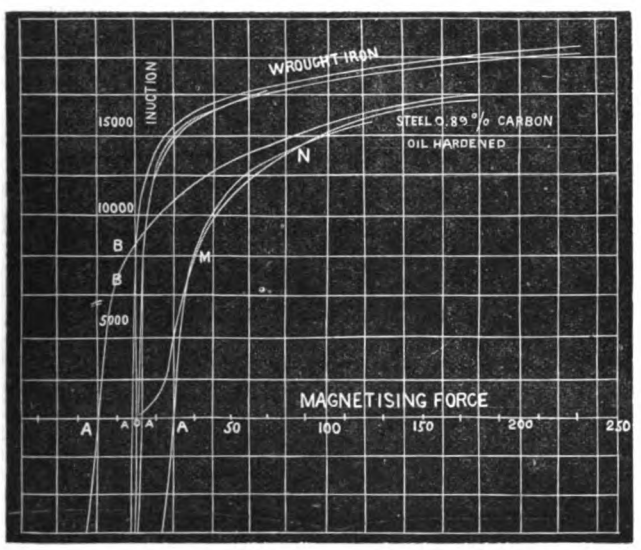

Fig. 3.

induction as measured by the galvanometer deflection is independent of the time during which the successive currents have acted, and depends only upon their magnitude and order of succession. Some recent experiments of Prof. Ewing, however, seem to show a well-marked time effect. There are curious features in these experiments which require more elucidation.

It has been pointed out by Warburg, and subsequently by Ewing, that the area of curve 2 is a measure of the quantity of energy expended in changing the magnetism of the mass of iron from that produced by the current in one direction to that produced by the current in the opposite direction and back again. The energy expended with varying amplitude of magnetising forces has been determined for iron, and also for large magnetising forces for a considerable variety of samples of steel. Different sorts of iron and steel differ from each other very greatly in this respect. For example, the energy lost in a complete cycle of reversals in a sample of Whitworth's mild steel was about 10,000 ergs per cubic centimetre; in oil-hardened hard steel it was near 100,000; and in tungsten steel it was near 200,000—a range of variation of 20 to 1. It is, of course, of the greatest possible importance to keep this quantity low in the case of armatures of dynamos, and in that of the cores of transformers. If the armature of a dynamo machine be made of good iron, the loss from hysteresis may easily be less than 1 per cent.; if, however, to take an extreme case, it were made of tungsten steel, it would readily amount to 20 per cent. In the case of transformers and alternate-current dynamo machines, where the number of reversals per second is great, the loss of power by hysteresis of the iron, and the consequent heating, become very important. The loss of power by hysteresis increases more rapidly than does the induction. Hence it is not well in such machines to work the iron to anything like the same intensity of induction as is desirable in ordinary continuous-current machines. The quantity O A when measured in proper units, as already explained—that is to say, the reversed magnetic force, which just suffices to reduce the induction as measured by the kick on the galvanometer to nothing after the material has been submitted to a very great magnetising force—is called the "coercive force," giving a definite meaning to a term which has long been used in a somewhat indefinite sense. The quantity is really the important one in judging the magnetism of short permanent magnets. The residual magnetism, O B, is then practically of no interest at all; the magnetic moment depends almost entirely upon the coercive force. The range of magnitude is somewhat greater than in the case of the energy dissipated in a complete reversal. For very soft iron the coercive force is 1·6 C.-G.-S. units; for tungsten steel, the most suitable material for magnets, it is 51 in the same units. A very good guess may be made of the amount of coercive force in a sample of iron or steel by the form of the ascending curve, determined as I described at first. This is readily seen by inspection of Fig. 3, which shows the curves in the cases of wrought iron, and steel containing 0·9 per cent. of carbon. With the wrought iron a rapid ascent of the ascending curve is made, when the magnetising force is small and the coercive force is small; in the case of the hard steel the ascent of the curve is made with a larger magnetising current, and the coercive force is large. There is one curious feature shown in the curve for hard steel which may, so far as I know, be observed in all magnetisable substances: the ascending curve twice cuts the descending curve, as at M and N. This peculiarity was, so far as I know, first observed by Prof. G. Wiedemann.

(To be continued.)

TEST OF THE NEW SPRAGUE STREET RAILWAY MOTOR.*

BY DR. LOUIS BELL.

A few weeks ago I had the opportunity to make a careful test of the new type of the Sprague motor, and the results, I think, are of sufficient interest to publish and discuss.

Most of the prominent American motors for street railway service seem to have settled down into a common and not altogether advantageous form; that is, a single magnetic circuit supported on the car axle at the yoke and furnished with a Siemens armature acting on the wheels through an intermediate gear. This form of magnet, although possessed of many advantages, makes a motor rather heavy in proportion to the power developed. A light weight motor constructed on this plan and having a relatively powerful armature is likely to have its field seriously distorted. The added weight necessary with this type is certainly a disadvantage for most purposes. American practice in this respect seems to be quite different from English practice, where a double magnetic circuit with consequent poles and an armature relatively quite powerful seems to be the rule, and this form of motor, such as is used by Reckenzaun and Immisch, weighs, for equal power, only about half as much as the American form of motor, while its electrical efficiency is quite as great. There may be mechanical reasons for the American practice, but the increased weight so decreases the economic ratio of the system, as explained in a recent Paper of mine, that efforts certainly should be made to build a lighter form of motor.

To illustrate this point, start to compute the economic ratio for a motor like the one under discussion, and then for a motor of the light-weight class. In the first case we may have a 16ft. car, weighing perhaps 3,000lb., carrying a full load of perhaps 4,000lb. of passengers, and motors weighing, as in the present case, 4,400lb. The ratio, then, between useful load and total weight is ·61. Com-

* From the *Electrical World* of New York.

Digitized by Google

pute now the same ratio for the same car and load of passengers, having, however, motors weighing but 2,500lb., a weight quite within the range of possibility. The ratio in this case will be ·77. It is therefore clear that even if the light-weight motor should have 10 per cent. less electrical efficiency it still would be the more economical. It ought to be quite possible to design a motor which should not weigh more than 80lb. per horse-power of normal output, and still retain a good electrical efficiency and reasonable freedom from heating. Such a motor would probably be somewhat greater in first cost, but its life should be very nearly as great as at present, and it certainly would be distinctly more economical in power than the present motors. Some of the Immisch motors for stationary service weigh less than 70lb. per horse-power output, and still have an electrical efficiency of 90 per cent. It should be remembered, however, that there is one case where the heavier motors are of service—when trailers are to be used extensively. In such case the increased tractional power gained by the added weight may well offset the disadvantages. Still a lighter form of motor is none the less necessary for those numerous cases where motor cars are alone employed or occasional trailers are used on light grades.

The new Sprague 15 horse-power motor has a single magnetic circuit, and the armature, instead of having a commutator at each end, has a single massive commutator containing 76 segments, with very narrow insulation between them. This change in the form of a commutator is a very decided improvement, both mechanically and electrically. The most marked difference between this new form of motor and the old one is, as is well known, in the winding both of armature and field, the resistance of the new motor being very much less. The connections with the switch-box are the same in each, and the resistances of the coupled motors, measured cold (about 65 Fahrenheit), are as follows :—

Step.	Old motors.	New motors.	Step.	Old motors.	New motors.
1	10·76	4·30	5	2·83	1·10
2	6·98	2·95	6	2·83	1·10
3	6·98	2·95	7	2·17	0·82
4	5·44	2·10			

The armature resistance of the old motor was about 1·2 ohms ; that of the new motor is less than one-tenth of an ohm. As a result of this difference the new armature is less likely to burn out than the old one. The gearing of the two motors, although different in detail, is about the same in effect ; in the old motor the armature makes 11·9 turns to one turn of the wheels, in the new motor 11¾ turns to one turn of the wheels. The new motor weighs 2,200lb., almost exactly twice the weight of the old.

The new motor was tested by running over a measured tenth of a mile on grade, noting the speed and measuring the electrical energy on the car by means of Ayrton and Perry ammeters and voltmeters. The grade was 6·58 per cent. on the same spot at which I had previously tested the old motor some months since ; the instruments used were the same in both cases, and the track, as nearly as I could judge, was in the same condition. The car, however, was but lightly loaded, and weighed about 7,800lb. complete. Runs were made up the hill on each step of the switch box, taking in each case a flying start, and the results were as follows : —

Step.	Rate.	Arm. Speed.	Watts.	E.H.P.
1	6·00	790	11,954	16·02
2	6·00	790	12,326	16·52
4	6·30	832	12,169	16·31
5	8·00	1,053	13,124	17·59
7	7·83	1,030	12,760	17·10

Some apparent discrepancies will be noticed in the above table. These are mainly due, I think, as they were in the previous test, to variations in voltage at the station. Computing now from these data the efficiencies of the motors we obtain far better results than with the old motor, as is shown in the following table :—

Step.	Motor E.H.P.	Motor E.M.F.	Electrical Efficiences.	
			New Motor.	Old Motor.
1	10·89	292	67·9	...
2	12·92	335	78·2	39·9
4	13·83	364	84·8	59·3
5	16·03	384	91·1	76·1
7	15·92	388	93·1	78·9

In the last column is given the efficiency of the old motor for comparison. It will be seen that electrical efficiency of the new motor is very high, and that consequently the heating is much less, especially in the armature, and the life of the coil must be correspondingly greater than in the old motor. In computing the above table 10 per cent. resistance was allowed for heating on steps two, four, and five, and 15 per cent. on steps one and seven, as these were taken last, and the heating, especially on step one, was severe compared with the heating on the other steps. At the completion of the test, which occupied about three-quarters of an hour, at the end of a full day's run up and down the same grade, the resistance of the coupled motors was again measured at the switch-box. The increased resistance gave approximately the amount of heating. The increase in resistance was nearly 16 per cent., which corresponds to a mean rise in temperature of about 72°F.

As to the commercial efficiency of the motors I can give no exact figures. The gearing being nearly the same as in the old motors, and the hysteresis being probably nearly the same—perhaps 500 watts—it is probably safe to allow nearly the same loss from these causes as in the old motor. I think one can safely say that the average commercial efficiency is somewhere about 75 per cent., possibly as high as 80. This is a distinct gain over the efficiency of the old motors.

It would seem that it should be possible to design a motor which should give satisfactory efficiency and yet need to be geared down but once. The intermediate gear is a constant source of noise and friction, which should be avoided if possible. With respect to efficiency, this new Sprague motor leaves little to be desired, but it is much to be wished that the skill of its designer could be further exercised to make a motor about two-thirds as heavy as the present one, and which would give at least as high a commercial efficiency as the old motor with an armature speed of 500 to 600 revolutions per minute. The task is not an easy one, but I do not think it at all impossible. Light weight and little gearing are two points which should in future be aimed at. It might be desirable even to have the armature act directly on the car axle without the intervention of gearing, but whether this advantage could be secured without too great a loss of efficiency and a too great increase of bulk and weight seems at present rather doubtful.

REPORT TO THE ST. PANCRAS VESTRY ON ELECTRIC LIGHTING.

BY PROF. H. ROBINSON, M.I.C.E.

The following is the report upon which the Vestry of St. Pancras recently resolved to ask for electric lighting tenders. The figures relating to scheme No. 2 have been omitted since the Vestry have decided to embark on the largest scheme :—

Gentlemen : Mr. Thos. Eccleston Gibb has thought that your convenience would be best met by my submitting to you in detail the cost of the two alternative installations of 10,000 and 5,000 lights which were suggested in my report of March last. The installation of 10,000 lights I will call scheme No. 1, the central station being in King's-road ; and the installation of 5,000 lights, with the central station in Edward-street, I will call scheme No. 2. At your meeting on the 14th October, the desirability of sub-dividing the contracts under several heads was referred to, and I stated that this would effect economy in carrying out the works. As I understood that you wished my estimates to be confirmed by tenders, I have gone very fully into the arrangement of the engines, boilers, dynamos, batteries, transformers, mains, &c., and have obtained provisional tenders from various leading manufacturers on which the figures hereinafter given are based.

The following is a description of the general arrangement of the works and of the system of producing and distributing the electric current. I propose to supply the consumers with a continuous current at a tension of 110 volts. The immediate neighbourhood of the central station will be supplied by a low tension (110-volt) dynamo feeding direct into the distributing mains, and the distant portions of the district will be supplied from sub-stations placed to suit the demand. The power will be transmitted from the central station, where it is generated, to the sub-stations by a constant continuous current, at a tension varying according to the demand, from about 500 volts to a maximum of 3,000 volts. This high-tension primary current will drive continuous current transformers at the sub-stations, and will produce secondary low-tension currents, which will be fed into the distributing mains. There will be a reserve of storage batteries, always charged, at each sub-station, which can be available as a stand-by in case of any sudden demand. The total amount stored will be about 800 units in No. 1 scheme (for 10,000 lights), and about 460 units in No. 2 scheme (for 5,000 lights).

The cost of producing a unit of electricity depends upon the size of the installation and upon the number of hours the lamps are used per annum, and I have prepared a table to show this in order that you may see clearly the advantage of commencing with an installation of 10,000 lights instead of with one of 5,000 lights. I have based my calculations upon the very liberal assumption that every additional 5,000 lights (beyond 10,000) will cost the same as the second 5,000 lights. The first column gives the number of 16 candle-power incandescent lamps which the plant is capable of

Digitized by Google

serving simultaneously. The number of lamps which may be safely installed will be considerably more than these, as it has been found in practice that the maximum number in use at one time lies somewhere between two-thirds and three-fourths of the number of lamps installed. The number of units sold per annum is taken at 80 times the number of lamps given in the first column for the first two cases, and then in diminishing proportion down to 70 times in the last case.

Number of lamps of 16 candle-power.	Cost of producing one unit (excluding sinking fund).
5,000	3·27 pence.
10,000	2·80 „
15,000	2·70 „
20,000	2·70 „
30,000	2·70 „

In calculating the above table I have taken non-condensing engines as being employed at the central station, which are less economical than condensing engines. The latter use about 25 per cent. less steam, saving therefore that percentage of coal and stoking, and this, with the reduction in depreciation of boilers, &c., represents about one farthing per unit. If condensing engines are employed, the above figures, therefore, would be reduced by about ·25 of a penny. No. 1 scheme is arranged for condensing engines, as the site admits of cooling the condenser water, but in No. 2 scheme I have provided for non-condensing engines, as the cooling of the condenser water at this site is likely to be affected by the surrounding buildings in Edward-street. The additional cost per unit to provide for the sinking fund may be safely taken at ¾d. in all cases, so that, after making due allowance for the sinking fund, the cost per unit will never exceed 4·02d. with non-condensing engines, or 3·77d. with condensing engines. These figures are arrived at after the details have been gone into, and may be accepted in place of the 4½d. per unit which I gave in my report of March. In my report of May I gave the price of an incandescent lamp up to 16 candle-power as 5s. I find that the present of these lamps is 3s. 9d., and this reduction in the cost of the lamp reduces also the cost of the renewals by a similar 25 per cent.

Scheme No. 1.

For 10,000 incandescent lights of 16 candle-power and 40 arc lights of 500 watts. The machinery at the central station (King's-road) is arranged for a maximum rate of output of 600,000 watts, delivered through five sub-stations, and 50,000 watts delivered direct to the mains, or a total output of 650,000 watts, which is equivalent to about 550,000 watts delivered to the lamps. The 10,000 incandescent lights will absorb 530,000 watts, leaving 20,000 watts to serve 40 arc lamps in the streets. There will be five sub-stations, arranged to supply as follows:—No 1, near the top of High-street, Camden Town; No. 2, near the middle of Albany-street; No. 3, near the south end of Hampstead-road; No. 4, near Goodge-street; No. 5, in or near Gordon-street.

Cost of Scheme No. 1.

Central Station, King's Road.

Buildings—Engine and boiler houses, foundation for engines, boilers, and dynamos, chimney and flues, offices, walls, gates, roads		£3,250
Tank for condenser water		540
Machinery—		
Five sets of Willans' II engines, combined with Siemens 120 unit dynamos	£7,750	
One set of Willans' GG engines, combined with Siemens 50-unit dynamo	800	
One 60-unit transformer	500	
Three boilers	2,250	
Surface condenser apparatus	1,000	
Feed pumps, steam mains, circulating pump, cooling apparatus, and travelling crane	1,050	
Regulating gear, electrical connections, instruments, tools, &c.	1,000	
		14,350

(These mains will serve fully 25,000 lights without additional feeders.)

½ mile with 2 sq. inches in each conducter	£1,725
½ „ 1½ „ „	1,425
1 „ 1 „ „	2,250
1 „ ¾ „ „	1,950
1 „ ½ „ „	1,650
2 „ ¼ „ „	2,500
Extra for divided main (*i.e.*, separate feeders) in ½ mile of above @ 3s. per yard	130
Extra for house junction T pieces, 6 miles @ £66 per mile	400
265 surface boxes or manholes	800
High tension mains, 9,350 yards at 8s. 6d.	3,880
Total cost of mains	£16,710

Summary of Cost of Scheme No. 1.

Central station	£18,140
Five sub-stations	10,360
Six miles of Mains	16,710
	45,210
10 per cent. contingencies	4,521
Total	£49,731

It will be noticed that the length of distributing mains included in the above estimate is six miles (or 10,560 yards), and 9,350 yards of high tension main. This latter length includes the return wires, and therefore only equivalent to 4,675 yards of double main. Adding this to the 10,560 yards of distributing main gives a total length of 15,235 yards, against the 22,000 yards stated in the Report of May (p. 13). The reason for the difference is that the six miles of distributing mains in the present estimate are made large enough to convey electricity to serve 25,000 lights working simultaneously, which, in my opinion, will be found to be the demand upon them. If the mains are laid at the outset of a size only to serve 10,000 lights distributed over the greater length of 22,000 yards of mains, their capacity will very soon be overtaxed, and it will then be necessary to take them up and lay larger ones, or to put down long lengths of additional feeders, at a cost which can be avoided by laying the mains as suggested. Small branch mains to serve 50 to 150 lights up side streets, where the demand is not likely to increase rapidly, can be laid at a cost of about £900 per mile.

The cost of running the arc lights will be as follows:—

500 watts acting for 3,808 hours per annum = 1,904 B.T. units at 3½d.	£27	15	4
Carbons and lamp lighter	10	16	0
Total	£38	11	4

40 lamps at £38. 11s. 4d. = £1,542. 13s. 4d. per annum.

These lamps would replace about 200 ordinary gas lamps, which now cost £560 per annum, so that the increase in cost would be £982. 13s. 4d. per annum, but with an increase of 14 times the present light, as stated in my May report. The prime cost of the 40 arc lights, if erected in the cheapest possible manner, would be about £1,000, or with ornamental posts and shelters about £3,000.

Annual Cost of Scheme No. 1 (Including Production of 825,000 Units).

Rent: Central station (ground)	£105	
Five sub-stations (cellars)	300	
		say £400
Depreciation of plant, &c.		3,400
Salaries: Engineers, assistants, and clerks		1,100
Labour: Engine drivers, stokers, &c.		1,500
Coal: 2,830 tons at 17s. 6d.		say 2,500
Water, oil, waste, and petty stores		500
Total annual cost		£9,400

to produce 825,000, or nearly 2¾d. per unit.

Annual Cost of Scheme No. 1 with Different Rates of Production.

The fixed expenses may be taken as follows:—

Rent	£400
Depreciation of plant	3,400
Salaries	1,100
Part of labour, coal, water, oil, stores, &c.	1,100
	£6,000

Annual cost when producing—

400,000	units = £7,666	or 4·60d.	per unit.
500,000	„ = 8,083	„ 3·88d.	„
600,000	„ = 8,500	„ 3·40d.	„
700,000	„ = 8,916	„ 3·06d.	„
800,000	„ = 9,333	„ 2·80d.	„
900,000	„ = 9,750	„ 2·60d.	„

If the current is used for motive power to any considerable extent, the plant will be able to meet a larger demand, as the motive power will be required at times when the machinery is not under full load for lighting purposes, and this will increase the revenue in a higher proportion than the working expenses, so much so that it might be well to encourage the demand for motive power by supplying the current at a lower price for that purpose.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *December* 28, 1889.

The Overhead Wire Cutting in New York.—You will readily infer that the wire-cutter has been busy in this city when I inform you that since the work begun recently, after the Court had removed the injunction protecting the overhead circuits of the various companies, 154 miles of wire and 535 poles have been cut down. The work would probably have been done more rapidly, but for the fact that the Commissioner of Public Works experienced the greatest difficulty in securing good linemen. It was hardly to be supposed that the linemen in this city, or from any other, would be very enthusiastic in coming forward to remove the poles and wires that have afforded them a means of livelihood. In fact, it is supposed to be against the rules of the linemen's union to take any part in such work. Hence the destruction has been hampered by being committed to men unfamiliar with the handling of wires, and to others whose method of handling the axe would indicate that they do not hail from the backwoods. As might be expected, the work was attended by more than one accident, and even now it can hardly be looked upon as complete, for much remains to be done. The wires and poles, however, are no sooner down than there is a change of front and a change of tone on the part of the newspapers. The New York *Times* has called for a resumption of the arc light service as rapidly as possible wherever it has been interrupted. The *Evening Post*, a prominent evening paper, has remarked that no city which has known and enjoyed the blessings of electricity will ever go back to gas. The New York *Sun* says there is no doubt that the electric light can be made safe, so far, at least, as ordinary contingencies go, and that its vast superiority to every other for public and very many private uses justifies any cost which such safety will render necessary. It adds: "The period of deprivation, therefore, will be short, and when the light is again made available for safe use in all parts of the town, the demand will be greater than before, and the cost of the improvement will be recompensed. The companies can afford to incur the additional expense now that it has been practically demonstrated that they provide the community with what is indispensable to modern life." With regard to what is immediately before us, it may be taken for granted that the companies will have a good suit against the city for the destruction of many of their circuits, which consisted of the best insulated wires known to-day for the purpose, and which were, undoubtedly, thoroughly adequate to all reasonable requirements of public safety. It mattered little to the wirecutters whether the circuits were good or bad. A wire was a wire, and away it went, whether its insulation was frayed and ragged underwriters', or whether it was the best that money and science could provide. The sudden change in affairs, too, has naturally stimulated the demand for underground wires and cables; but it will, no doubt, be several weeks before these can be got ready, since they not only have to be made, but the delicate work of splicing has to go on under the unfavourable conditions of winter. It is said that the cables in the subways are now giving better results than were expected. This is probably true, although it is not less a fact that a great deal of cable work put in as recently as twelve to eighteen months ago, has already succumbed, and has had to be taken out. And then, moreover, there is the question whether the new subways, which have been rushed at such a great rate, will not develop serious defects when they come to be used. It is possible, moreover, that we may continue to have subway explosions. One occurred only last week, and was so complete a performance in its way that one wonders how on earth the passers-by escaped.

The Government v. the Bell Telephone Company.—It is worth while to note in passing that the Government is continuing its work with regard to the prosecution of the suit of the United States against the Bell Telephone Company. This suit, as I may remind you, was brought mainly on two grounds—first, that the Bell patent was obtained by fraud, and, next, that Daniel Drawbaugh was a prior inventor. The other prior inventors of whom we have heard so much seem to have been relegated to the background, but if one may judge from what the Pennsylvania papers say, a good deal of importance is attached by the Government lawyers to the work of the old blacksmith of Eberly Mills. An examiner is now taking testimony at Harrisburg, and, of course, we have the re-appearance of the country fakirs, who say that they used the telephone in Drawbaugh's workshop away back in 1873 and 1874. The supporters of Drawbaugh claim that they have important new evidence to bring forward, but it is hard to believe that at this late date, after the case has been so thoroughly thrashed out, there is anything to be developed to which the word "important" can properly be applied.

A Challenge to the Edison System.—The United Electric Light and Power Company and the United States Illuminating Company, of this city, have issued an open challenge to the local Edison Electric Illuminating Company for an expert investigation of their respective systems of electric lighting. The challengers complain that the challengee has been spreading incorrect and misleading statements about the converter system of incandescent lighting, and has tried to influence the Board of Health against it.

The Progress of the Alternating System.—It is interesting, in this connection, to call attention to the fact that the alternating system is still having rapid development in this country, and that there is no slackening in the demand. According to figures published by the Westinghouse Electric Company, their shipments of alternating current apparatus for eleven months of the year 1889, ended November 30th, amounted to a capacity of 223,600 16 candle-power incandescent lamps. During the entire year 1888 the total amount of business represented a capacity of 106,200 16 candle-power lamps, and during 1887 119,950 16 candle-power lamps, making for those two years a total capacity of 226,150 16 candle-power lamps. From these figures it is not difficult to gather the fact that the total amount of business done by the Westinghouse Electric Company during the year 1889 will more than double the amount of last year's business, and it will even exceed the combined amount of the business accomplished during 1887 and 1888. It is to be borne in mind that this is not the whole of the alternating-current business, since the Thomson-Houston Company, the Brush Company, the Fort Wayne Company, and one or two others are also supplying the field, and are nearly all of them doing a large business.

The "Double-Carbon" Lamp Patent.—Many of your readers will, doubtless, be interested to learn that at Indianapolis, Ind., on December 24th, in the United States Circuit Court, Judge Gresham decided a suit brought by the Brush Electric Company, of Cleveland, against the Fort Wayne Electric Light Company for infringing the Brush patent upon the so-called "double-carbon" lamp. The case has been vigorously prosecuted and defended, and has been pending about three years. All of the claims of the Brush patents are sustained, six in all, and declared to be infringed. These claims cover the all-night electric lamps used for street lighting, where two or more pairs of carbons are employed, one pair being first burned and then another automatically consumed. The patent was attacked by the defence mainly upon the grounds that its claims were too broad and sweeping, but this defence did not avail. It is worthy of note that both the litigants are now controlled by or in alliance with the Thomson-Houston Company.

SCANDINAVIAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

COPENHAGEN, *December* 31, 1889.

The telephone does not seem able to extend fast enough in Sweden, where both State and private enterprise are working with a will for the advancement of telephony. As I have already mentioned the Swedish Government has granted 750,000kr. (£40,000) for State telephones, to be expended at the rate of 150,000kr. (£8,000) per annum. The line taken in hand for the year 1890 is that between Stockholm and Malmö. For the following year the State Telegraph officials contemplate erecting a line between Stockholm and Hernösand, with a branch to Sollefiia. One use of the telephone which has been adopted in Sweden, has proved very serviceable in

Digitized by Google

a great many instances: Steamers, while in port, are joined to the telephonic system. Of course the steamers must have the necessary appliances on board, but it is evident that this arrangement is a very practical and time-saving one, which would assuredly prove most desirable in a number of English ports.

The reduction which took place in the charge for inland telegrams in Sweden at the beginning of the present year has brought about a very material increase in the number of telegraphic messages despatched. During the first nine months the number of inland telegrams exceeded the number for the corresponding period of 1888 by 243,797 telegrams, or about 54 per cent., while the receipts were almost identical with the figures for the previous year. During the same period the number of foreign telegrams had risen 2 per cent., and the receipts 4 per cent.

The town of Bergen, in Norway, is contemplating the erection of a central station. A representative of the Thomson-Houston International Electric Company is on the spot explaining the merits of that Company's system. The Corporation is willing to grant a concession, but not a monopoly. The capital required is about £20,000.

A large telephone company for Western Norway is about to be formed, and application has been made to the Government for a concession. A considerable portion of the necessary money has already been subscribed.

The immense distances at which a powerful electric light can be seen has just been forcibly illustrated by the new electric light-house at Houstholm, the light of which has been sighted from outside Mandal, Norway, a distance of about 70 miles; also from Fläkkerö, at Christiansand, Norway. The flashes from Houstholm have been seen high up in the air as narrow rays.

The Östermalur church at Stockholm has just had electric light installed, and is the first church in Sweden which has been lighted in this manner. The installation was carried out by the firms of Luth and Rosen and the Elektriska Bolaget, Stockholm. The cold weather recently experienced at Stockholm has caused a lot of breakages on the telephone wires. Both the telephone companies have had many broken wires, resulting in a large number of interruptions.

The electrical engineers in Sweden and Norway, more so than in Denmark perhaps, are busy, and not only do the various installations materially increase, but the manufacture of various electric appliances is also extending. The Great Northern Telegraph Company at Copenhagen is going to build a very handsome block of houses for offices, &c. The building is in the principal square of the city.

CORRESPONDENCE.

THE HOUSE-TO-HOUSE STATION AT WEST BROMPTON.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I notice that in *The Electrician* of January 3rd, under the heading "Central Lighting Stations of the United Kingdom, London," the West Brompton Station of the House-to-House Electric Light Supply Company (Limited), is described as using "the alternating current (Parker Alternators and Transformers)," which is incorrect, the system in use being the same as adopted at Eastbourne and Brighton, viz.: The Lowrie-Hall System of Alternating Current Transformers. I should feel obliged if you will kindly insert this letter in the next issue of your valuable paper. Thanking you in anticipation,—Yours, &c., CHARLES J. HALL, Manager.

Kensington Central Electric Lighting Station,
January 6, 1889.

LEGAL INTELLIGENCE.

Inland Revenue Department v. the Mines and General Telpher Company.

Before Messrs. J. McCall and S. L. Stacey and Major Taylor, the divisional justices sitting at the Edmonton Petty Sessions on Saturday last, the Mines and General Telpher Company (Limited), of 12, Great George-street, London, appeared to answer a summons, issued at the instance of William Leghorn, officer of Inland Revenue, for having, on August 17th, at the parish of Wood-green, kept five carriages, for the keeping of each of which a licence was required by the statute, without having proper licences.

Mr. ROBINSON, who conducted the prosecution, said the case was an important one from the point of view of the Inland Revenue authorities, because it was the first case of the kind which had been brought forward in the neighbourhood of London, if not over the whole of the United Kingdom. The offence with which the company was charged was that of having an electric tramway, and running thereon five carriages carrying passengers from the entrance to the Alexandra Park to the doors of the Alexandra Palace, the carriages being unlicensed.

Mr. CHRISTIE, who appeared for the defence, said his clients considered that their line was a railway, and they did not wish to avoid the payment of any duty for which they might be held liable by the Bench. This was a new invention, and they wanted to find out what they were really liable for. He contended that his client's cars did not come under the definition of a carriage, because they did not ply for hire, and could not be stopped like a tram car between the fixed stations.

The CHAIRMAN of the BENCH, after a consultation, said they were disposed to find that the carriages referred to in the summons did not come within the definition of a carriage subject to taxation. The Bench thought it was a sufficient reason of exemption that they ran on rails, though it was not a statutory railway.

Mr. ROBINSON intimated that the decision would be appealed against.

The South of England Telephone Company.

The Recorder of Brighton (Mr. P. C. Gates, Q.C.) had before him on Monday and Tuesday an appeal by the South of England Telephone Company against the poor rate. The overseers had assessed the property of the Company in the parish at £650 and £500 rateable value. The appellants, while admitting that the wires connecting the telephone were rateable, contended that the telephones themselves, and the apparatus connected with them, were chattels, and, therefore, not rateable, and as to the rateable value of their property, showed that it was a minus quantity of £985. Mr. Poland, Q.C., and Mr. Besley represented the appellants, and Mr. Castle, Q.C., and Mr. Gore the respondents. The witnesses for the appellants were Mr. Ponsford, solicitor to the Company; Mr. Francis Cowley, district superintendent; and Mr. Charles Barker, engineer and surveyor, of London. For the respondents Mr. W. Castle, F.S.I., and Mr. W. H. Ellwell, surveyor-in-chief to the Great Northern Railway Company, were called. The Learned Recorder reserved judgment until next Quarter Sessions.

TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning.*]

"THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK, 1890.—We call the attention of the electrical public to the fact that entries for insertion in the Alphabetical and Classified Trades Sections of the forthcoming edition cannot be inserted in their proper places unless received immediately.

TENDERS WANTED.—Our advertising columns contain a notification that the Guardians of the Poor of the Sheffield Union are desirous of obtaining tenders for connecting the various parts of their workhouse buildings to the fire station by electric bells.

TELEPHONE PATENTS FOR SALE.—Particulars will be found in our advertising columns of several telephone patents which are for sale.

ELECTRIC LIGHTING IN SOUTH WALES.—To demonstrate the great strides which electric lighting is making in popular favour, we may mention that Mr. J. C. Howell, of Llanelly, has, within the year 1889, installed 65 arc lamps, and over 3,500 incandescent lamps in South Wales, besides other electrical work, such as electrical transmission of power for pumping plants in the Rhondda collieries, &c.

THE ENDOLITHIC IVORY COMPANY (LIMITED).—We are requested to notify that this company are now connected by telephone, No. 21.

STANHOPE PATENT TELEPHONES.—The latest list of the Stanhope Company gives illustrative particulars of the Stanhope patent electro-magnetic telephones, which are sold outright without royalty, and which are guaranteed not to infringe the National Company's patents. Accompanying the sheet of prices, &c., is a list of many large establishments where the Stanhope telephones are in use.

BELL'S ASBESTOS COMPANY (LIMITED).—We have received from this firm a very useful, well-printed Calendar for 1890, and a revised list of the new-pattern cocks and water-gauges made by the firm. These are neatly illustrated in section. These cocks and gauges are made to any design or measurement, although the price list under notice gives examples of only a few of the regular sizes.

FITCH BATTERY AND ELECTRIC COMPANY, NEW YORK.—The catalogue and trade list of this Company contains illustrated particulars of the "Chlorine" battery, for telephone, telegraph, electric bell, and other open service work. From the testimonials accompanying the list, the battery is in good repute in the States.

PATENT RECORD.

APPLICATIONS FOR PATENTS.

19,861A. C. H. Logan. London. Improvements in plates for secondary voltaic batteries.
[This application having been originally included in No. 19,681, dated December 10, 1889, takes, under Patents Rule 23, that date.]

December 21, 1889.

20,565. C. H. Bell. London. An arrangement of electric light for steamers' chart table, or for a reading desk.
20,582. J. Einstein and S. Kornprobst. London. Improvements in electric meters and indicators.

December 23, 1889.

20,627. W. M. Mordey. London. Improvements in electric distribution.
20,645. J. A. L. Dearlove. London. New or improved means for protecting the metallic coating of telegraph cables from corrosion.
20,646. G. A. Cassagnes. London. A new or improved printing telegraph apparatus.
20,652. J. W. Edmundson and W. Clarke. London. Improvements in incandescence electric lamps.
20,653. W. Foster and C. Griffiths. London. Improvements in covers or protectors for telegraphic insulators.
20,660. J. O. Winckler. London. An improved electric signalling apparatus.

December 24, 1889.

20,717. H. S. Prentiss. London. Improvements in electric cams.
20,734. R. Huddan. London. Improvements in magneto-electric machines (C. F. Gillette, United States).
20,751. F. Marx. London. Improvements in electrical accumulators.
20,752. F. Marx. London. Improvements in the manufacture of electrodes for electric batteries.
20,764. W. P. Thompson. Liverpool. Improvements in or relating to armatures for electric machines (Westinghouse Electric Company, United States).

SPECIFICATIONS PUBLISHED.

1888.

14,161. Bollmann. Producing electro-magnetic inductions. (Price 1s. 3d.)
18,331. Holt. Electro-dynamic engines. (Price 8d.)
18,450. Johnson (Bradley). Dynamo-electric machines. (Price 11d.)

1889.

915. De Ferranti. Electric switches. (Price 8d.)
1,057. Adams-Randall. Electric date, &c., stamps. (Price 11d.)
1,823. Coleman and Jackson. Telephonic apparatus. (Price 8d.)
2,137. Gwosdeff. Magnetic telephony. (Price 8d.)
2,252. King. Measuring electric currents. (Price 6d.)
2,299. Desruelles and Chauvin. Measuring electric currents. (Price 6d.)
2,413. Wright and Moore. Printing telegraphs. (Price 6d.)
3,130. Fraser. Telephonic instruments. (Price 6d.)
6,628. Scott and others. Electrical underground mains. (Price 8d.)
11,018. Weems. Electric railways. (Price 1s. 1d.)
11,300. Lake (Van Choate). Electric lamps. (Price 6d.)
11,615. Reed and McKibbin. Electrical railway conduits. (Price 8d.)

COMPANIES' MEETINGS.

United River Plate Telephone Company (Limited).

An extraordinary general meeting of this Company was held at Winchester House, Old Broad-street, on Thursday, under the presidency of the Right Hon. Lord Thurlow.

The notice convening the meeting having been read by the Secretary (Mr. J. Owen Unwin),

The CHAIRMAN said that the object of the meeting was to authorise a financial operation of two-fold significance. In the first place they desired to increase the working capital by the sum that was now required for their extended operations, and which, as he would proceed to point out presently, was perfectly justified by the extensions they were making in several directions; and in the second place they wished to take that opportunity of reducing the rate of interest that they paid for their debenture debt. He thought they would agree with him that the position which the Company now occupied was not one which justified their continuing to pay 7 per cent. annually for their Debentures, and the best proof of that was that the Board found that there was no difficulty in converting them into a 5 per cent. charge. The net result of the operation when it was fully carried out—at least when it was carried out to the extent proposed at the present time—would be to give the Company an issue of £150,000 for only £500 a year more than they now paid for the use of £100,000—that was to say, that they would have to pay £500 a year, or 1 per cent., for the use of an additional £50,000. He thought that would be regarded as a very favourable financial operation. He would like now to give a few figures indicative of the progress the Company had made. When they commenced business, as nearly as possible three years ago, the number of subscribers was about 3,200. The capital at the commencement of the Company, as would be remembered, was £250,000 in shares and £50,000 in debentures, making a total capital of £300,000. That represented a capital as nearly as possible of £94 per head per subscriber. The number of subscribers on October 31, 1889, at Buenos Ayres, La Plata, and Rosario, was about 5,300, and the present capital amounted to £290,000 in shares and £100,000 in debentures, making a total of £390,000; and if they calculated that out, adding about £8,000 since spent, it would be found to amount to as nearly as possible £74 per head per subscriber, instead of £94. That was to say, that they had over half as many additional subscribers, and the proportion to capital expenditure was reduced by 20 per cent. That was, he thought, a very favourable condition of things, showing—and he had no doubt of it whatever—that as time went on and if the number of subscribers increased at the rate at which it had hitherto done, the cost in proportion to capital would fall in about the same ratio. There were one or two other things that he would like to trouble the meeting with before they proceeded to the resolutions proposed to be submitted. He thought they might rely upon the position they occupied that day being certainly very much stronger and sounder than the one they occupied at the commencement of their business, and he felt sure if it had not been so it would not have been so easy for the Directors to come before them and suggest their taking such a course as that which was now under consideration; and he thought the best proof that he could adduce of the existing strength of their position and their prospects of success was the fact that they came now before the shareholders with their proposals at a time when the bank rate was 6 per cent., and when they could not borrow money in the streets of London much under 7 per cent., and when the price of gold at Buenos Ayres was 135 per cent. He thought these two circumstances were more eloquent than any words of his could possibly be, and could not fail to satisfy even the most critical of shareholders of the wisdom of their policy. He was bound to say that all the letters they had received—and they had received a great many from absentee shareholders who were unable to be present on that occasion—had expressed, with but two or three exceptions, complete satisfaction

with what it was proposed to do. He was glad, however, that there were some shareholders present, because it was always satisfactory to hear by word of mouth any criticisms that could be made. But he felt sure that no criticism could be made as to the course they were adopting that day which could not be easily and satisfactorily answered. As regarded future expenditure, they had received inquiries as to what the estimated cost would be for the trunk line that they proposed to make between Buenos Ayres and Rosario, to connect their new exchange at Rosario with the old and large exchange at Buenos Ayres. The cost would depend on circumstances, and on how the business developed, as well as on the number of metallic circuits that would have to be laid down, but there was every prospect of that trunk line being made with the utmost possible economy. They would follow the line of the existing railway between Buenos Ayres and Rosario. The railway company had met them in the most friendly spirit, and had promised to afford them in the future the most ample facilities for carrying out the work, so that he could assure the shareholders that, whatever the cost might be, they might rest satisfied the trunk line would be constructed on the most economical principles consistent with efficiency. As regarded figures, he need not go into details. With respect to other expenditure, of course their system was growing, and they had to connect new streets, new houses, and new suburbs. All that took money, but there were certain opportunities afforded, as those extensions were rendered necessary, of affecting economies; and they would be blind to their own interest if they did not incur a little expense for the sake of perfecting their arrangements as they went along. He might mention that, for existing extensions which they were compelled to make, £8,000 as nearly as possible had already been spent. They did not propose at the present moment to go to the full extent of the issue for which they asked powers. They proposed to issue additional capital for expenditure just now to the amount of £29,000. There was only one other point to which he wished to draw attention, and it was a matter which had come only too prominently before them, and that was the extraordinarily high rate of gold at Buenos Ayres, which had curtailed their dividend by nearly one-half at the present time. That was a circumstance which they on this side had no control over. It was an unfortunate circumstance, but he thought it was on the whole satisfactory to know that the prosperity of the Company was such as enabled it to withstand so great a strain on its profits, and at the same time be able to offer what was no inconsiderable dividend to the shareholders. He believed the Company in the future would pay from, say, 5 to 7 per cent. dividend in bad years, and from, say, perhaps, 10 to 12 per cent. in good years. He did not like to prophesy, and anything he said must be subject to circumstances such as those he had alluded to, over which the Directors had no control; but, reasonably speaking, he did not see why the anticipations he had attempted to foreshadow as to their earnings in the future should not be fulfilled. He then moved:

"*That debentures or debenture stock of the Company providing for the payment of principal sums not exceeding in the aggregate £200 000, be created and issued at such times, in such manner and form, on such terms and conditions, bearing such rate of interest, with such stipulations as to redemption at a premium or otherwise, and secured in such manner as the Directors shall think expedient. Provided that so long as any of the existing debentures of the Company which fall due on January 1, 1907, shall be outstanding or uncancelled, the nominal amount of the new debentures or debenture stock from time to time issued under this resolution, together with the nominal amount of the existing debentures so outstanding or uncancelled, shall not exceed the sum of £200,000.*"

Mr. J. IRVING COURTENAY (Deputy-Chairman) seconded the resolution, which was unanimously adopted without discussion.

The CHAIRMAN then moved and Mr. COURTENAY seconded the next resolution as follows:—

"*That the Directors be and they are hereby authorised to redeem all or any of the existing debentures by exchanging them for any of the new debentures or debenture stock, or by payments in cash, or in such other manner and at such premium or rate of exchange as they shall think expedient, and that pending the issue of the new debentures or debenture stock, the Directors be and they are hereby authorised to borrow on such terms as they may think fit any moneys for the purpose of redeeming any of the existing debentures, or for any other purposes of the Company.*"

The resolution having been carried unanimously, a vote of thanks was passed to the Chairman, and the proceedings terminated.

NEW COMPANIES REGISTERED.

ELECTRICAL STANDARDISING, TESTING, AND TRAINING INSTITUTION.—This institution is formed to establish, maintain, and carry on in England or elsewhere any standardising, testing, or calibrating institution or institutions, where all or any electric measuring instruments can be tested, calibrated, or standardised, and for other like purposes. Capital £10,000, in £5 shares, of which the first 100 are founders' shares. Subscribers of one share each are: W. A. Pitman, 7, St. Helens-gardens; James Whitehead, electrical engineer, Crouch End; Thomas E. Towerson, F.C.S, analytical chemist, 1, Portland-road, Finsbury Park; H. Linklater, accountant, 117, Bishopsgate-street; R. Acock, secretary, same address; J. A. Roxburgh, clerk, same address; and Oscar W. Seligman, 3, Moreton-gardens, South Kensington.

SYNDICATE OF ELECTRICAL ENGINEERS.—The objects, capital, and signatories to the Memorandum of Association of this syndicate are the same as those of the Electrical Standardising, Testing, and Training Institution above.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended January 3rd amounted to £4,974.

CUBA SUBMARINE TELEGRAPH COMPANY.—The estimated traffic receipts of this Company for the month of December, 1889, were £3,000, as compared with £3,508 in the corresponding month of last year. The receipts for the month of September, estimated at £2,400, realised £2,372.

DIRECT SPANISH TELEGRAPH COMPANY.—The traffic receipts of this Company for the month of December were £2,137, against £1,908 in the corresponding period last year, an increase of £279.

DIRECT UNITED STATES CABLE COMPANY (LIMITED).—The Board of this Company have resolved upon the payment of an interim dividend of 3s. 6d. per share, free of income-tax, being at the rate of 3½ per cent. per annum for the quarter ending December 31, 1889, such dividend to be payable on and after the 24th instant.

EASTERN TELEGRAPH COMPANY.—This Company's traffic receipts for the month of December amounted to £56,862, as against £59,834 in the corresponding period of 1888, a decrease of £2,972.

EASTERN EXTENSION TELEGRAPH COMPANY.—The traffic receipts of this Company for the month of December were £40,362, as against £38,699 for the same period of 1888.

GLOBE TELEGRAPH AND TRUST COMPANY.—This Company have declared an interim dividend of 1s. 9d. per share, payable on the 18th inst.

GREAT NORTHERN TELEGRAPH COMPANY.—The traffic returns of this Company for the month of December amounted to £22,400. From January 1st to December 31st they were £274,800, against, in the corresponding months of 1888 and 1887, £272,200 and £264,480 respectively.

SCHANSCHIEFF ELECTRIC BATTERY SYNDICATE.—An extraordinary general meeting of the Schanschieff Electric Battery Syndicate (Limited) was held on Monday last at the offices, 44, Basinghall-street, E.C., for the purpose of considering a resolution for the voluntary winding up of the Company and the appointment of liquidators.

WEST COAST OF AMERICA TELEGRAPH COMPANY.—The traffic receipts of this Company for the month ended December 31st amounted to £6,375.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The receipts of this Company for the half-month ended December 31st amounted to £2,643, against £2,392 in the corresponding period last year, an increase of £251.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended January 3rd, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited) were £3,682.

PERSONAL.—Mr. Charles Burt has been appointed a director of the Anglo-American Telegraph Company, in place of the late Sir Daniel Gooch.

THE NON-CONDUCTOR OF ELECTRICITY.

VULCANISED FIBRE,

PATENTED.

This new material is supplied in two qualities, Flexible and Hard.

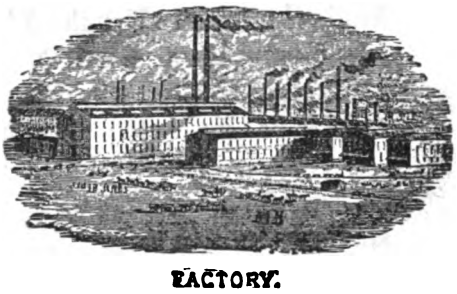
The FLEXIBLE is a substitute for Leather, Rubber, Gutta Percha, &c., and is extensively used by Brass Founders, Axle Makers, Hydraulic, Sanitary, and other Engineers, Pump Makers, Carriage Builders, &c.

It makes the best Hot and Cold Water Packings, and for Axle Washers of all kinds it is unequalled.

The HARD is a substitute for Metals, Hard Wood, Ivory, Vulcanite, Ebonite, &c., and is a good Insulator.

Sold in sheets, 5ft. 6in. by 3ft. 6in., varying in thickness from 1-50th. to 1in.

FLEXIBLE, 2/- per lb.; HARD, 2/3 per lb.



FACTORY.

MOSSES & MITCHELL, 70 Chiswell-st., London, E.C.

JABLOCHKOFF'S
DISTRIBUTION PATENT

(Being a Patent for "Producing and Dividing Electric Light," No. 1996 of 1877.)

THE UNITED ELECTRICAL ENGINEERING COMPANY (LIMITED)

Are Proprietors of the above Patent, and Warn the Public against Infringement.

The following are Licensees:—

Anglo-American Brush Electric Light Corporation, Limited.
Crompton & Co., Limited.
S. Z. de Ferranti.—London Electric Supply Corporation, Limited.
W. T. Goolden & Co.
Hammond & Co.
Wilson Hartnell.
Johnson & Phillips.
Laurence, Paris & Scott, Limited.
Nalder Brothers & Co.
Paterson & Cooper.
Ernest Scott & Co.
Siemens Brothers & Co., Limited.
J. G. Statter & Co., Limited.

3, Prince's Mansions, Victoria Street, Westminster.

MANVILLE & MADGEN, *Managing Directors.*

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 609.—Vol. XXIV. FRIDAY, JANUARY 17, 1890. Price Fourpence.

NOTES.

The terms in which the retiring President of the Institution of Electrical Engineers spoke last week of the achievements of submarine cable laying, and of the eminent men associated with it who had virtually founded the profession of electrical engineering, were at once appropriate and well-timed. No one is better qualified to offer an opinion on these points than Sir W. Thomson, and his public testimony, coupled with the election of Sir James Anderson, Sir Albert Cappel, and Sir Henry Mance to the Council of the Institution, will afford much satisfaction, we doubt not, to the members generally, but especially to that numerous and influential group of them who sympathised with the complaints which found expression recently in our correspondence columns.

Before quitting this subject, however, we have a less agreeable task to perform in connection with it. The Institution some time ago resolved to exclude reporters from its meetings; and although we questioned the policy of this decision, we have loyally abided by it. Last week's proceedings were of such importance, however, that we made inquiry as to whether any exception would be made on that occasion, and were answered in terms which practically precluded us from sending our reporter. It will now be seen that we print this week the remarks of Sir W. Thomson commented upon above, but that we are indebted to *The Times* for that privilege. Of course it is possible that *The Times'* reporter may have been present disguised as a Member of the Council; but the more probable theory appears to be that what is denied to the electrical press is conceded to the all-powerful thunderer.

We publish this week some important regulations relating to the supply of electricity which it is the intention of the Board of Trade to enforce in connection with all methods of electrical distribution. These regulations are at present only in draft form, and it may be anticipated that they will receive considerable modifications at the hands of the various authorities and bodies interested, to whom they have been submitted. This latest contribution of the Board of Trade to the already formidable array of electric lighting rules and regulations, although it bears the impress of having been drawn up to some degree under the influence of recent transatlantic events, does not, taken as a whole, lay down conditions impossible of attainment in ordinary everyday commercial distribution.

It will be observed that the Board of Trade have wisely abandoned their hard and fast current density rule for conductors, and have substituted for it a temperature limit. On the other hand, in Section 7, they lay down that the insulation resistance of any complete circuit used for a high-pressure supply shall be such that, should any part of the circuit be put to earth, the leakage current shall not exceed one twenty-fifth of an ampere and one-fiftieth of an ampere for continuous and alternating currents respectively. A maximum percentage leakage would, we think, be a more practical test. In Section 6, again, it is laid down that "the insulation resistance of any high-pressure conductor including joints shall not be permitted to fall below *fifty megohms per mile*." We would suggest to the Board of Trade, firstly, that it would be as well to employ the more rational and correct method of specifying insulation resistance in *megohm miles*; and, secondly, that in adopting such a minimum they are seeking to impose an impossible standard on electric supply companies. At Hastings, for instance, where the standard is rather above than below the average, the product of the length in miles into the total insulation resistance in megohms of any circuit at no time exceeds 3·7 and often falls much below this figure; yet we do not hear either of disastrous short circuits or of fatal accidents. Fifty megohm miles therefore seems to us an absurdly high figure. The clauses relating to the compulsory testing of faulty indoor wiring and to the compulsory cutting off of the supply until such installations are put into proper order cannot but commend themselves to all who wish to see an end put to fires and other mishaps due to careless and cheap wiring. There are several other points in these regulations which call for comment, and we should be glad to have the opinions of those most nearly concerned upon them.

In our advertisement columns will be found an announcement on the part of the Lea Bridge, Leyton, and Walthamstow Tramways Company, which is tantamount to a challenge to electric traction to come and do its best on these suburban lines. The Company is about to invite fresh tenders for the horsing of its cars for twelve months or more, and is prepared to guarantee payment for a minimum mileage of 250,000 to 300,000 miles. Being, however, in the possession of Parliamentary powers to work its system by electricity, the Company announces its perfect readiness to substitute electric for horse traction if an acceptable offer is forthcoming. One or other of the electric companies owning traction patents may, we feel confident, be trusted to take up this challenge.

Digitized by Google

THE New York *World*, with a painful degree of enterprise, has apparently made up its mind to start an electrical scare of its own, and instead, therefore, of devoting its energies to "writing up" the accidents which are reported to have recently taken place in the "Empire City," it has commenced a series of sensational articles on the dangers of electric traction. The following graphic description of a supposititious accident to a Boston electric car will enable our readers to form an idea of the style of this series:—"Suddenly by reason of a slight catch of the trolly-wheel on a point of the overhead wire, the latter falls on the car. . . . A circuit is formed, and we all know what a shock of this kind means. You may picture the stiffened corpses that are removed through doors and windows."

PROF. H. S. CARHART contributed to the *Philosophical Magazine* for November a Paper, which we publish elsewhere, on the construction of the Clark cell. Despite all the work that has been done on this standard of electromotive force, we are still in the dark as to some of the causes of small variations in it. When these doubts are all cleared up, and the process is ascertained of constructing cells absolutely uniform in E.M.F., and the temperature coefficient is accurately known, it will constitute a standard of great utility. At present it just falls short of being perfect.

WILLIAM STURGEON, the inventor of the electro-magnet, is one of those worthies whom every electrician should hold in pious remembrance. We are glad to be able to call attention to a letter in another column of this week's issue from Prof. SILVANUS THOMPSON, in which he asks for information respecting the deceased worthy. Prof. THOMPSON is particularly desirous of obtaining a portrait of STURGEON: we do not remember to have seen one. We trust that there may be some amongst our readers who are in a position to furnish a clue. STURGEON was a Lancashire man, and doubtless there are those still living both in London and in Manchester who knew him personally.

AN esteemed correspondent writing from Madeira reminds us of an unfulfilled duty which we ought to have discharged long ago. It appears that some remarks of ours relating to the suggested use of the telephone in America as an adjunct of the Confessional were so worded as to give pain to members of the Roman Catholic Church; and our attention was called to the fact soon after the occurrence, but in a letter of such unusual length that we have never yet been able to find room for it. As the incident is now more than twelve months old, we can do no more, but at the same time no less, than frankly admit that the note complained of was unfortunately, but unintentionally, open to the construction put upon it. Our correspondent furnished a long and convincing list of Roman Catholic divines and laymen—Volta among the number—who have been devoted to scientific pursuits, together with abundant evidence that the Church is not hostile to scientific progress as such. Obviously the objection to telephonic confession would be on practical or disciplinary grounds, not because the medium was a scientific appliance.

THE amalgamation of the UNITED ELECTRICAL ENGINEERING COMPANY and Messrs. J. G. STATTER and Co., under the title of the Electrical Engineering Corporation (Limited), is another satisfactory sign of the times, since it has been mainly effected with a view of enabling the two firms to cope with their daily increasing volume of business. The works of the Corporation at West Drayton are admirably situated in many important respects, and we anticipate the best results from the fusion of two such energetically managed concerns.

Barmen.—An electric tramway will shortly be constructed between Elberfeld and Barmen.

New Books.—M. Hospitalier has begun the publication of a work in two volumes, entitled "Traité Elémentaire de l'Energie Électrique."

Southampton.—The Town Council have decided to oppose the Provisional Order of the South of England House-to-House Electricity Company.

Harrogate.—The Town Council have decided to oppose the application of the National Electric Supply Company for a Provisional Order.

Ayr.—The Town Council have obtained a Provisional Order for lighting the Burgh with electricity. A committee is considering the subject.

The Davy Medal.—The Davy Medal has been awarded to Dr. W. H. Perkin for his researches on magnetic rotation in relation to chemical constitution.

Weybridge.—Considerable dissatisfaction is felt with regard to the electric light wires and posts, and an agitation is on foot for putting the wires underground.

The Tudor Accumulator.—The *Börsen Courier* learns that the Allgemeine Electricitäts Gesellschaft, Berlin, has purchased the Tudor Accumulator Manufactory at Hagen.

Coventry.—At the last meeting of the Town Council it was decided to oppose the application of the Midland House-to-House Electricity Company for a Provisional Order.

Berlin.—According to the Berlin correspondent of the *Standard*, Herr Werner Siemens intends shortly to retire from business, in order to devote himself entirely to scientific work.

The Telegraph in Afghanistan.—The Amir purposes, says *Indian Engineering*, to open telegraph lines from Kabul to Kandahar, Kandahar to Herat, and Herat to Mazrsharif probably.

St. Marychurch Local Board.—The Devon and Cornwall Electricity Supply Company will not proceed with their Provisional Order covering the area within the jurisdiction of this Board.

Cardiff.—At the last meeting of the County Council resolutions were passed objecting to the applications of the Brush Electric Engineering Company and the Western House-to-House Electricity Company.

Royal Visit to Canford House.—In view of the visit of the Prince and Princess of Wales, Canford House has been redecorated and provided with the electric light, over 1,000 lights having been put in.

The St. Petersburg-Moscow Telephone Line.—The trunk wire connecting St. Petersburg and Moscow was completed a few days ago, and although it is of iron, satisfactory results are reported to have been obtained.

The Western and Brazilian Company and the Brazilian Republic.—The *Rio News* of December 23rd states that the Western and Brazilian Telegraph Office was under official control from the 18th to the evening of the 20th.

Walsall.—At the meeting of the Town Council on Monday the General Purposes Committee reported that they had caused the common seal to be affixed to the memorial to the Board of Trade for the Electric Lighting Provisional Order.

Digitized by Google

Melbourne.—The rapid extension of electric lighting at Melbourne has caused the insurance companies to take into consideration the promulgation of rules and regulations with regard to electric light installations in Victoria.

The Electric Light in New Zealand.—The town of Lawrence (New Zealand) is to be lighted by electricity. The price charged for the light to consumers is not to exceed what would be equivalent to 6s. 8d. per thousand cubic feet of gas.

Telegraphic Communication with Martinique.—The contract with subsidy entered into between the West India and Panama Telegraph Company and the island of Martinique, which expired on December 31, 1889, has been renewed for one year.

Dockyard Central Stations.—Following the example of the Admiralty, the French Minister of Marine has directed the dockyard officials to draw up plans and estimates for the erection of central lighting stations in the various dockyards of France.

Leamington.—At the meeting of the Town Council the report of the Watch Committee, which was in favour of a deputation being appointed to visit a number of towns with the view of recommending the best system of lighting, was adopted.

Royal Society.—Since the last anniversary of the Royal Society 24 memoirs have been published in the Philosophical *Transactions*, containing a total of 753 pages and 33 plates. Of the *Proceedings*, 12 numbers have been issued, containing 1,062 pages and six plates.

Electric Lighting Tenders.—Tenders, which must be sent in by February 1st, are invited for the public lighting of Wildungen by gas or electricity. The Municipality of Berne also invites tenders for the electric lighting of the town; the tenders to be sent in by February 15th.

The Metropolitan Provisional Orders.—The Electricity Supply Corporation have abandoned their Paddington Order. The same Corporation have also abandoned their proposed Order for the lighting of the district of St. Giles' District Board of Works and the district of the Strand Board of Works.

Atlantic Cables.—The steamship "Faraday," has reached the Thames, after successfully laying two cables from Nova Scotia to New York for the Western Union Telegraph Company, and repairing the fracture in one of the main Atlantic cables. The second task was performed on the last day of 1889 in stormy weather.

Extension of the Oerlikon Works.—The Oerlikon Electrical Works are about to undergo considerable extensions, and it is proposed to obtain motive power from Burlach, twenty kilometres distant. According to *La Lumière Electrique*, an alternating current at a pressure of 25,000 volts is to be employed for the purposes of transmission.

Sunderland.—The Corporation have decided to oppose the Provisional Order of the Newcastle and District Electricity Supply Company, the basis of the opposition being the amount of capital to be deposited, the area of supply, the period within which the works are to be completed, and the control over the streets exercised by the company.

Personal.—Mr. J. Carruthers Allan has been appointed superintendent for the African Direct and West African Telegraph Companies at Bonny, West Coast of Africa, and has resigned his position of Danish Consul for the Colony of Lagos. He has been succeeded in that appointment by Mr. S. J. Boffa, who is at present representing the first-mentioned company at that place.

Brussels.—At a recent meeting of the Communal Council, M. Janssen announced that the electric light would be installed in Brussels by the end of the present year. The Council will reserve for its municipal station a zone of a quarter of a mile radius from the Market-place. The area comprises nearly all the theatres, the largest shops, as well as the central boulevards.

Royal Meteorological Society.—The annual meeting of this Society was held on Wednesday evening. The Council in their report stated that the total number of Fellows is 550, being an increase of 25 on the previous year. Mr. Baldwin Latham, M.Inst.C.E., was elected President for the ensuing year, and the retiring president, Dr. Marcet, then delivered an address on "Atmospheric Dust."

The Despatch of Cablegrams by Mail Steamers.—The Eastern Telegraph Company has made arrangements with the English Post Office authorities by which cablegrams will be received at the Mauritius Post Office, and despatched by the mail steamers to the nearest cable stations. A similar arrangement is being negotiated with the French Government in respect to Réunion and Tamatave.

The Provincial Electric Lighting Orders.—The National Electric Supply Company have, it it understood, decided not to proceed with their Barnsley Order, thus leaving the Order deposited by the Corporation of Barnsley unopposed so far as that company are concerned. The same company have also dropped their proposed Order for the electric lighting of Hull, for which the Corporation have deposited an Order with the Board of Trade.

Marylebone Vestry.—At a meeting of this Vestry last week it was agreed that notice should be given to the Metropolitan Electric Supply Company that where vaults exist under the footway pavements of any of the streets of the parish, the mains of the company shall be laid only in the roadway of such streets; and, further, that the company must deposit a sum of 2s. in footway and 3s. in roadway per lineal yard wherever operations are commenced.

Exeter.—At the last meeting of the Town Council Councillor Varwell moved, "That in view of the serious nature of the report presented by the surveyor and fire superintendent as to the overhead electric lighting cables, and the imperilling thereby of the public safety, the Electric Lighting Company be informed that the Council cannot consent to any further extension of their overhead wires." After a lengthy discussion the motion was lost by 22 votes to 10.

St. George's (Hanover-square) Vestry.—At the last meeting of this Vestry the Electric Lighting Committee recommended the Vestry to petition against the London Central (Subway) Railway Bill, in order to obtain a *locus standi*. An amendment was moved that the Bill should be opposed by counsel. After a long discussion the amendment was carried by 30 votes to 19. Another amendment to refer the matter back to the committee was negatived by a large majority.

Newcastle.—At the last meeting of the Town Council, the Town Improvement Committee presented a report relative to an application by the Northern House-to-House Electricity Company, for a Provisional Order. The committee did not think it desirable that a third company should supply electricity in Newcastle. It was agreed that objection be lodged with the Board of Trade. The Newcastle and District Electric Lighting Company have commenced to supply current.

Dundee.—At the last meeting of the Police Commission the application of Mr. Caird for permission to erect an overhead electric wire from Ashton Works to his house in Magdalen Yard-road was considered. The question was discussed at great length. The Lord Provost and several members were in favour of granting the request, since the current was only to be at a pressure of 50 volts. It was, however, finally decided by 13 votes to 10 to refuse the application.

Reading.—Mr. Yeatman, local manager of Messrs. Laing, Wharton, and Down, having agreed to light by electricity the Free Library and Museum for a sum less than the gas lighting has hitherto cost, the Town Council have authorised the Library Committee to close with the offer, and the installation will be proceeded with without delay. In business houses electricity is being widely adopted as an illuminant, the number of installations being so great that Messrs. Laing, Wharton, and Down have had to supplement their original plant by extensive additions. The 1,200 candle-power arc lamp is almost exclusively used.

Hertford.—At a recent meeting of influential gentlemen resident at Hertford, held under the presidency of the Mayor, the subject of initiating a scheme for supplying the electric light in the borough was discussed. It was suggested that a company should be formed, with a capital of £20,000 or

Digitized by Google

£25,000, to carry out the scheme; and this was eventually agreed to—a committee being nominated to take the necessary steps in the matter. It was stated that the required capital could be easily obtained; and, with regard to the possible success of the undertaking, it was confidently expected that most of the tradesmen in the town would take the light.

The Lighting of the City.—At the meeting of the Commissioners of Sewers on Tuesday, the clerk submitted an application of the London Electric Light Corporation for the Commissioners' consent to their application for a Provisional Order; also a similar application from the Metropolitan Electric Supply Company. Mr. Innes moved that these applications do lie on the table. He said they had already settled the matter so far as the Brush Company was concerned, and they had given them a contract to carry out the electric lighting on the terms arranged by the Streets Committee. It would be most unfair to the contracting company if they agreed to these fresh applications seeking Parliamentary powers over the City. The Commissioners must be masters in their own place. After some discussion Mr. Innes' motion was agreed to almost unanimously.

Old Students' Association.—On Wednesday, January 29, at 8 p.m., a special general meeting of this Association will be held at the Central Institution, Exhibition road, for the consideration of certain important changes in the rules. In their fourth annual report the committee state that the register now embraces 194 names—honorary members 7, members 158, associates 29. During the past session 61 new names have been added—43 members and 18 associates. On June 25, 1889, the following resolution was unanimously passed by the committee:—"That Prof. John Perry, F.R.S., D.Sc., be, and hereby is, elected an honorary member of the City and Guilds of London Institute, Old Students' Association, as some slight recognition of the strong and unremitting interest he has manifested in the affairs of the Association since its inception." The committee further report that there are usually more vacancies than applicants on the employment register. The Papers read before the Association were examined by Profs. Unwin, Henrici, and Armstrong, and the Medal of the Association was awarded to Mr. Heller for his Paper on "Aluminium." The accounts of the Association show a satisfactory balance.

Obituary.—It is with deep regret that we record the death, on December 26th, of Mr. Jean François Despointes, whose name is well known in submarine telegraph circles. Mr. Despointes was born on November 4, 1816, at Barfleur. He came to England at the age of 20. In 1854 the then chairman of the Submarine Telegraph Company offered him the post of translator to the company. In 1858 he was made superintendent-in-chief, a post which he occupied without intermission until his death. Mr. Despointes took a great interest in all that related to scientific progress, and from his position in the Submarine Company he was constantly brought into connection with those desirous of making experiments upon submarine lines. It was in this way that he was able to afford considerable assistance to Sir Charles Wheatstone, Prof. Hughes, Dr. Muirhead, M. Baudot, and others. In 1864 he assisted in the experiments made by the Russian Government between Caucasia and Valentia, Ireland. He was a member of the Institution of Electrical Engineers, the Society of Arts, the Société Internationale des Electriciens, and numerous other societies in England and France.—The death is also announced of Mr. Charles Henry Chadburn, founder of the well known firm of Chadburn and Son, telegraph manufacturers, of Liverpool. Mr. Chadburn took an active part in the business up to the time of his retirement a few years ago.

The Glasgow Corporation and Overhead Wires.—At the last meeting of the Town Council, a minute was submitted from the Special Committee on Overhead Electric Light Cables and Wires. It contained a report on the subject from Messrs. John Carrick, master of works; William Paterson, inspector of fires; and David Cook, electrical engineer. From this report it appears that there exist at present in Glasgow 3½ miles of overhead conductors carrying high-pressure alternating currents, and 1¾ miles of overhead conductors carrying low-pressure continuous currents. The report concludes as follows: "We would, however, fail in our duty were we not to express in the strongest manner possible our conviction that the present methods of conveying the currents overhead are such as to expose the citizens to serious risks of life and property, and that some change upon the existing arrangements should be effected without any delay." The Committee, having considered the report, agreed that it was necessary to take steps to bring the circumstances under the notice of the Board of Trade, and to urge on the Board the adoption by them of the procedure for the protection of the public safety under the Electric Lighting Acts. The Clerk was also directed to intimate to Messrs. Muir, Mavor, and Coulson (Limited) that the Magistrates and Council have had this matter under consideration, and had communicated with the Board of Trade in reference thereto. The minutes were approved.

The Penny Postage Jubilee Dinner.—At the Penny Postage Jubilee Dinner on Wednesday evening Sir Lyon Playfair, in the course of his speech, alluded to the late Mr. Scudamore in the following appreciative terms:—"On a day of rejoicing and remembrances like this let me say a word of appreciation of one of the greatest and best officials in the history of the Post Office—I allude to the late Mr. Scudamore. When I entered upon my duties as Postmaster-General he was in official difficulties with the Treasury and Parliament, because in his zeal he had used the revenue of the department for the rapid extension of the system of telegraphs. Of course, this was a grave official error, for the money ought to have been voted by the House of Commons. I entered the office believing that I would have much trouble with this impetuous secretary, but I left it feeling the highest admiration of his administrative capacity and unselfish zeal. The country owe him a debt of gratitude for the rapid and efficient extension of the telegraphic system. One night of anxiety remains vividly in my memory. The new Post Office buildings, with their fine telegraphic halls, were ready, but it was an anxious thing to disconnect the whole telegraphic communication of the country and re establish it in the new building. Mr. Scudamore was equal to the occasion, and the change was made without the loss of a single message or more than one hour's delay. Like so many of our friends Mr. Scudamore has gone to the great majority, but his memory should not be forgotten on this occasion."

Bradford.—At the meeting of the Corporation on Tuesday, a resolution was included in the minutes of the Gas and Electricity Supply Committee, authorising the present expenditure of a sum of £10,000 in extending electric light works, and appointing Mr. Sydney Baynes managing engineer at a commencing salary of £250 per annum.—Alderman Fred. Priestman, in moving the adoption of the minutes, reminded the Council that some few weeks ago the committee obtained permission to secure additional borrowing powers to the extent of £30,000. When they started the installation at the end of September they had only demands for 330 amperes, but they were now supplying 1,520 amperes. This had exceeded the most sanguine expectations of the members of the Council. They had now increased demands which they could not grant, as already the apparatus was somewhat overstrained. This being the state of affairs the committee was anxious that before next winter they should be able to supply the demand. Besides the outside application they had also had a requisition through the Mayor from the Recorder asking that the electric light should be placed in the Borough Court, and the School Board also required it. The buildings erected were sufficient for supplying four times more current than they did at present, and consequently the fixing of further apparatus would go towards making the system pay. At present they charged 5d. per unit for the electric light, but if that did not pay it would be their clear duty to increase the price.—Mr. Galloway opposed the resolution. He said that when the electric lighting scheme was first mooted the expenditure was to be limited to £20,000, but now another £10,000 was to be spent, and there was a further £20,000 in the background. He thought the committee should stay their hands until the experiment had been fairly tried, and it were seen if it were a financial success.—The minutes were adopted.

MAGNETISM IN IRON AND OTHER METALS.*

BY PROF. J. A. EWING, F.R.S.

III.

(*Continued from page 212.*)

§ 12. **Magnetic Force within the Metal.**—The magnetic force due to external causes—that is, to magnets or electric currents in the neighbourhood—which has just been described as constituting one part of the magnetic force which we should measure in a crevasse, is to be thought of as acting also within the uncut substance of the metal itself. It constitutes the whole magnetic force there. We shall denote the magnetic force by **H**. We must bear in mind that in reckoning the value of **H** at any point within the substance of a piece of magnetised metal, we have to take account not merely of the forces due to electric currents and to terrestrial magnetism and to the poles of other magnets, but also the forces which are contributed by the poles of the piece itself with which we are dealing.

§ 13. **Magnetic Induction.**—The whole group of lines which cross the crevasse is to be conceived as existing within the metal before the crevasse was cut, partly as lines of magnetisation and partly as lines of force. The whole group of lines which cross the imaginary crevasse consists (per square centimetre) of the resultant of $4\pi\mathbf{I}$ and **H**. This resultant is called the *magnetic induction* within the metal, and is denoted by **B**. The quantities $4\pi\mathbf{I}$ and **B** are vectors, having direction as well as magnitude, and are to be compounded as forces or velocities are compounded. If **H** and **I** happen to have the same direction, **B** is numerically equal to the sum of $4\pi\mathbf{I}$ and **H**. In any case the equation

$$\mathbf{B} = 4\pi\mathbf{I} + \mathbf{H}$$

is true when understood in the vector sense, that **B** is the resultant of $4\pi\mathbf{I}$ and **H**. In most of the cases that are of practical interest **H** has either the same direction as **B** or it has the opposite direction, so that the above equation holds good in the numerical sense when the proper sign (+ or −) is given to **H**, according as it assists or opposes the magnetisation.

§ 14. **Distinction between Magnetic Induction and Magnetic Force within the Metal.**—The lines of magnetic induction (**B**) within the bar are continuous with the lines of magnetic force in the space outside—that is to say, every Line of Force outside is completed, so that it forms a closed curve, by a Line of Induction inside. For many purposes **B** is the most important quantity by which the magnetisation of a magnet may be specified. In a dynamo, for instance, it is in the value of **B** in the armature core that determines the strength of the magnetic circuit. The analysis of **B** into two components, **H** and $4\pi\mathbf{I}$, is no doubt highly artificial, but it is of service when we have to deal with the relations which exist between the magnetism of a magnet and the influences which are affecting its magnetism from outside. The student will find it useful to picture to himself the state of a magnet at any point of its substance by thinking of two groups of lines as passing through the metal, namely, $4\pi\mathbf{I}$ and **H**, which combine to form a resultant group **B**. To obtain **B** directly we have only to imagine a narrow crevasse cut across the magnet: **B** is measured by the force a unit pole would experience if placed in such a crevasse; in other words, it is the number of lines which cross the crevasse per square centimetre of cross-section. If, on the other hand, we wish to isolate the magnetic force **H** that acts at any point within the metal, we may imagine a hole drilled through the magnet from end to end in the direction of magnetisation, and passing through the point at which **H** is to be measured. The force which a unit pole would experience if placed in the hole at that point is **H**. That this is so will be evident when it is remembered that there is no free magnetism on the sides of the hole, because it is supposed to be drilled in the direction of magnetisation, and the force within it is, therefore, due solely to the outside influences which give rise to the magnetic force **H**, as defined in § 12, namely, the free magnetism at the ends of the magnet and any other magnets or currents that are near.

* All rights are reserved.

§ 15. **Particular Cases.**—The following illustrations may help to make these definitions intelligible. Take a ring electro-magnet consisting of an iron core, wound with a solenoid of n turns per centimetre, and let a current, C, flow in the solenoid. The magnetic force within the solenoid, due to this current, is approximately equal to $4\pi\mathrm{C}n$ at all points. If there are no neighbouring magnets or other sources of magnetic force, this is the value of **H** which acts on the metal of the ring. Next, let the ring be cut and straightened into a bar, with the solenoid still on it, through which the current C flows. The magnetic force due to the current is still sensibly equal to $4\pi\mathrm{C}n$ (except near the ends). But we now have another term to consider in reckoning **H**. The free magnetism residing at the ends of the bar produces magnetic force at all points in the interior, as well as at points in the space outside, and **H** is the resultant of this force, together with the force $4\pi\mathrm{C}n$ due to the current. The force due to the free magnetism at the ends is opposite in direction to that due to the current; hence **H** at any point within the metal is less than $4\pi\mathrm{C}n$ by an amount which depends on the distance of the point considered from the ends of the bar. The longer the bar is the more nearly will **H** be identical with $4\pi\mathrm{C}n$, and if the bar is very long, so that the ends are too far removed to have any material influence, we may take the magnetic force on central portions as sensibly equal to $4\pi\mathrm{C}n$.

Again, in a permanent bar-magnet there is at any point a certain magnetic force, **H**, due to the free magnetism at the ends, and opposite in direction to the lines of magnetisation within the metal. We may call this the *self-demagnetising force exerted by the bar*, since its tendency is to reduce the bar's magnetisation.

Again, a long piece of straight iron wire stretched in the direction of the lines of force of the earth's magnetic field is acted on by a magnetic force, **H**, equal to the force of the earth's field. If the wire is hung vertically it is convenient to treat the earth's field as consisting of a horizontal and a vertical component. The former is a magnetic force which acts across the wire; the latter is in this case much the more important of the two, for it constitutes the whole longitudinal part of the magnetic force **H**, and, as we shall presently see, it is upon this almost wholly that the magnetisation of the wire depends.

§ 16. **Magnetic Permeability.**—In general, when a substance is placed in a magnetic field it becomes magnetised. We may express the connection between the magnetism it acquires and the magnetic force which acts upon it in two ways.

One of these ways is to compare the magnetic induction **B** which is produced in the metal with the magnetic force **H** to which that induction is due. For most purposes this is the best way.

To fix the ideas let us think of a very long uniform rod placed in a uniform field of magnetic force, with the direction of its length parallel to that of the lines of force. When the rod becomes magnetised its ends disturb the field of force, but we can get rid of any trouble about the ends by thinking of the rod as indefinitely long, or so long that the influence which the ends have on the value of the magnetic force is negligible. Let the uniform magnetic field exert a certain force, **H**, on the rod. This produces within the rod a certain induction, **B**, the value of which might be measured by cutting a narrow crevasse across the rod at any place, and measuring the number of lines per square centimetre which cross the crevasse.

If the rod is of iron, nickel, or cobalt, it will be found that the number of lines of induction **B** per square centimetre within the rod is much greater than the number of lines per square centimetre in the field. This fact may be expressed by saying that the material of the rod is more *permeable* by lines of magnetic induction than is the space or medium surrounding it. In Faraday's expressive language, the material of rod has greater conductivity for the lines of induction than the surrounding space or medium has. We may think of the lines as crowding by preference into the rod, finding an easier path through it than through the surrounding medium.

The quality in virtue of which the material of the rod conducts the lines better than empty space conducts them, is called its *magnetic permeability*. This phrase was introduced by Sir William Thomson in his mathematical development of the subject, as a

Digitized by Google

synonym for Faraday's "Conducting power of a magnetic medium for lines of force."

In the case we have supposed, of an indefinitely long rod, the magnetic force at any point within the metal has the same value as the magnetic force at any neighbouring point in the space outside, since the force is not disturbed by the magnetisation of the rod. In such a case we might define the permeability as the number (per square centimetre) of lines of induction **B** in the rod to the number (per square centimetre) of lines of force in the space outside. But if we wish a definition which will be of more general application—applying to short rods as well as to long ones, and to other forms of magnet—we have to bear in mind that the surrounding field is generally disturbed by the magnetisation of the piece. What has to be compared is the induction at any place in the metal with the magnetic force which is in operation there; in other words, we may define the permeability as the ratio of the induction **B** at any point of the metal to the magnetic force **H** which acts within the metal at that point. The permeability is usually denoted by μ; so that we have

$$\mu = \frac{\mathbf{B}}{\mathbf{H}}.$$

In this definition it is to be understood that **B**, the magnetic induction, has been produced by subjecting the material to a magnetic force, **H**.

§ 17. **Permeability of Paramagnetic and Diamagnetic Substances.**—A paramagnetic substance is one in which the permeability is greater than that of empty space. In other words, when such a substance is placed in a magnetic field it will become magnetised in such a way that **B** is greater than **H**. The lines of force of the surrounding field will converge more or less towards it, preferring it to the neighbouring space as a magnetic "conductor." Iron, nickel, and cobalt are paramagnets with exceedingly great permeability.

In a diamagnetic substance, on the other hand, the permeability is less than that of empty space. When such a substance is placed in a magnetic field, the lines of force more or less avoid it as a bad "conductor," preferring the space outside. No substance is more than slightly diamagnetic Even in bismuth, which is the most highly diamagnetic substance known, the magnetic permeability is very little less than unity: its value is about 0·9997.

The permeability of air is sensibly the same as that of empty space. Hence, when a magnetic field is formed in air, the lines of induction are indistinguishable from the lines of force. It is only when the lines pass into a substance which is either paramagnetic or diamagnetic that the distinction between magnetic force and magnetic induction must be maintained.

§ 18. **Illustrations of Permeability.**—By way of illustrating the behaviour of paramagnetic and diamagnetic substances when placed in a magnetic field, Fig. 5 and Fig. 6 have been copied from one of Sir William Thomson's Papers.* In Fig. 5 a magnetic field which was originally uniform has been disturbed by having placed in it a sphere of exceedingly permeable material. Before the sphere was placed in the field the lines of force were straight, parallel, and equally spaced. The effect of introducing the sphere is to make them converge upon it in the manner which has been exactly represented in the figure from which Fig. 5 is copied. Outside the sphere the lines may be called indifferently lines of induction or lines of force (§ 17). The lines inside, which have been added in this copy, are continuous with them, and are lines of induction. The magnetic induction within the sphere is uniform. Fig. 5 may be taken to represent what happens when a homogeneous spherical ball of soft iron is placed in an originally uniform magnetic field.

Fig. 6 shows in the same way how an originally uniform field of force is disturbed by the introduction of a sphere of diamagnetic material. The material here is a purely imaginary one, with permeability barely one-half that of the surrounding medium, and is more highly diamagnetic than any actual substance.

The student will not fail to notice that the convergence or divergence of the lines of induction, illustrated by these typical cases, depends on whether the permeability of the body is greater or is less than the permeability of the medium in which it is placed. If the surrounding medium were itself a paramagnetic substance, the case shown in Fig. 6 might be realised by choosing for the material of the spherical ball a substance whose permeability was about half (more exactly 0·48 times) that of the substance surrounding it.

We shall return to these figures later, in speaking of the influence which the form of the body that is placed in a magnetic field exercises on the amount of magnetic induction within the body.

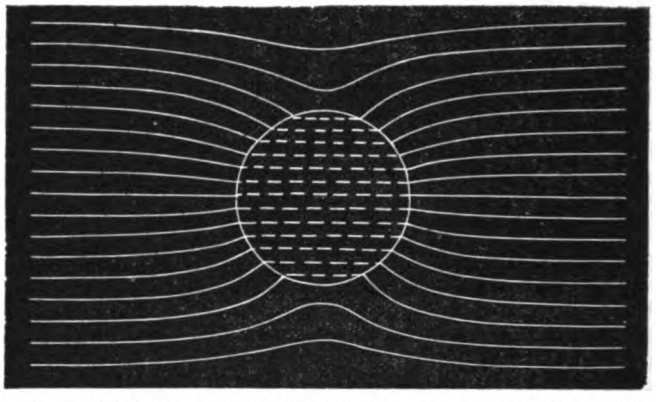

Fig. 5.—Disturbance of an originally uniform magnetic field by the introduction of a soft iron sphere.

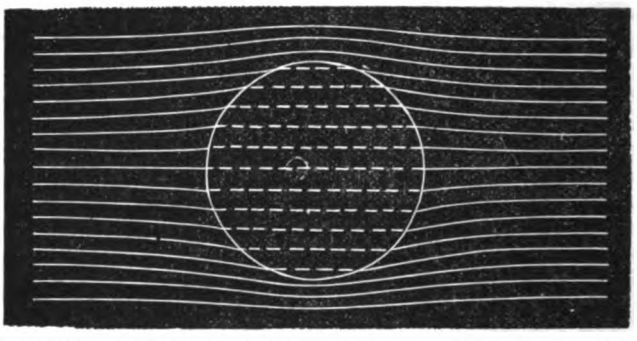

Fig. 6.—Disturbance of an originally uniform magnetic field by the introduction of a sphere of some diamagnetic material.

§ 19. **Magnetic Susceptibility.**—When a substance is magnetised by subjecting it to the action of magnetic force, the relation of the induction **B** to the force **H** measures, as we have seen, the permeability of the substance. But instead of expressing the magnetisability of the substance by stating the relation of the induction **B** to the force **H**, we may state it in a different way by giving the relation of the intensity of magnetisation **I** to the force **H**. The ratio of the intensity of magnetisation to the magnetic force producing it is called the *magnetic susceptibility* of the substance, and is usually denoted by κ; thus

$$\kappa = \frac{\mathbf{I}}{\mathbf{H}}.$$

UNDERGROUND MAINS.

BY G. L. ADDENBROOKE.

To the electrical engineer this is probably the most interesting subject of the day, but at the same time, though it may seem paradoxical to say so, it is not a very popular one. A certain amount of thought spent in designing dynamos, switches, and other kinds of electrical plant, will often produce an impressive result; but a great amount of thought spent on underground mains, even if productive of useful work, will usually fail to attract very much attention. It is one of those subjects which is chiefly approached by those who have to face it, not by those who choose it because they like it. Underground mains

Digitized by Google

up to the present have not been an easy subject to write about, and with a few exceptions all the information we have concerning them of a practical nature is fragmentary and disjointed. Such descriptions as have appeared of different systems when of any length and detail, have chiefly been of what inventors proposed to do, and not of what has actually been achieved.

Yet underground conductors are things which need the closest observation and scrutiny in all their details, though, unfortunately, they are by no means easy to observe and scrutinise. The laying of underground mains successfully needs an alert and instructed mind, but it is a class of work which such minds as a rule do not hanker after, and there can be little doubt that a good deal of the ill success which has attended the use of underground mains and conduits so far has been due to the laying of them having been left in hands which were not fully alive to the needs of the case. Once a system has been successfully carried out and has stood the test of time, its further use becomes in a large measure a matter of routine, but while the system remains in a tentative state, intelligent supervision and observation of even the minutest details are a matter of great moment.

The whole subject of underground mains is one of innumerable details rather than of a few broad principles. Each of the systems which have been devised gets over some difficulties well, and is less successful in respect of others; there are weak points in every system, and it is therefore important not to condemn outright any method of laying underground mains, because it has failed in some particular, since it is probable that a modified method of going to work on this point may still lead to success. Again, we must beware of thinking that there is one system of underground mains which must be the best. If there were one system of distributing electric current at one potential, no doubt some one system of conduits and mains would be found most suitable, but at present we are distributing current at different voltages for different purposes, and it is not to be supposed that any one system will prove the best for all these purposes.

Though we may calculate with certainty that as we become more familiar with the control of the current in large quantities, and under commercial conditions, the general tendency will be towards the use of higher voltages, yet we are now settling down by a gradual process of evolution to a fairly defined set of pressures at which current will be distributed in towns. The voltages which we are settling down to use now, and which, since the commercial interests involved are getting large, will not readily be changed, are as follows:—

1. 220—250 volts continuous-current supply at low pressure, using the three-wire system.

2. 500 volts continuous. A pressure which is being found very suitable for tramway working, and for use with motors, and which, though less used at present than the other pressures, seems not unlikely to be more employed in the future, particularly if a good 220 or 250 volt lamp should be discovered, which is by no means impossible.

3. 1,000 volts alternating. The American standard for distribution with transformers, and also the standard adopted by the Metropolitan Electric Light Supply Company (Limited), of London.

4. 2,000—2,500 volts alternating. The European standard for distribution by alternating currents.

5. 2,500—3,500 volts continuous. The general pressure adopted for working arc light systems on a large scale.

6. 10,000 volts alternating. The pressure Mr. Ferranti proposes to use at Deptford for primary distribution, employing two transformers between the central station and the consumer.

It is quite clear that currents at such different pressures as these will require different means for conveying them, and confining them to the conductors. At one end of the series we need a great section of copper, but only a moderate amount of insulation; at the other end of the series the section of the copper is relatively very small for the power conveyed, but the pressure of the current being very great much more elaborate precautions must be taken to insure that the insulation employed will stand the strain put upon it.

Before proceeding directly to describe the methods of constructing underground mains which are finding most favour with electrical engineers at present, it may be worth while briefly to allude to earlier experiences in similar classes of work. Now there are three sources from which we can draw a great deal of information of this kind.

The first is the early history of the mains used for conveying gas. In almost all cases some protection is being used for the conductors which carry the electric current, and in designing these coverings the experience met with in the early days of gas main-laying will stand us in good stead, if carefully noted.

The second and more important source is the experience of the telegraph companies, and, later on, the Post Office authorities with underground conductors. The early telegraph companies went in for underground conductors to an extent that few people who were not of years of discretion at that time have an adequate idea of. This battle of conduits and underground mains was very fully and thoroughly fought out then, and almost all the various constructions which have within the last two or three years been suggested were at that time tried. Most of them failed, or were defective in some particular or other, which caused them to be abandoned. It does not follow that because they failed then, therefore, that they should fail again when tried under better conditions now; but in any case a knowledge of what was found to be their weakness then should lead us to be cautious about that particular point now, and unless we can see that improved construction in this portion is likely to get rid of the defect, to be very careful in using the method.

The third and most important source from which we can draw experience is in the results obtained with the different methods of construction which are already in use by electric lighting companies so far.

When gas lighting was first introduced the manufacture of pipes was in a comparatively crude state, and iron pipes were only just beginning to be used for water, and it was still a moot point how the joints should be made. Small iron pipes were at the time unknown; gun barrels joined together were for some time used as a substitute, and it was a good while before the method of welding up wrought-iron pipes out of hoop iron was invented, and later on their manufacture by machinery. The manufacture of lead pipes also was in a very imperfect state, especially as regards the larger sizes. It was not until a great many experiments had been tried that the present methods of constructing gas mains were finally adopted. Amongst other things both wood and earthenware mains were tried, sheet-iron mains covered with lead, and mains of zinc and smaller pipes of papier maché. Wooden mains could not be kept tight at the joints, and earthenware mains were found to be too inflexible and fragile, though earthenware had an extended trial, and was only abandoned when, in spite of its cheapness, its marked inferiority to iron mains for conveying gas could no longer be doubted.

It is true that in the case of gas the chief object was to prevent the gas leaking out at the joints, while in electric conduits there is nothing of the same nature to leak out; still there is the tendency of water to get in, and this tendency with pipes buried two or three feet would in some places be greater than that of gas to escape, since it is easy to imagine a head of 12 or 14 inches of water trying to get in at the joints when the pipes are buried in ground saturated with water. Some authorities have said, I am aware, never mind about a little leakage, only provide drains to carry it off; but this does not seem to be a wise maxim for practice. From condensation and other causes water has a tendency to get into conduits any way, and if it does not do any actual harm, it lowers the margin of safety. Therefore the less we have of it the better, and the more efficient will be our means of dealing with it if we do not have to cope with large quantities or sudden and unexpected flows.

With respect to the laying of iron pipes and their lasting qualities, there is plenty of experience to guide us, which will be found fully detailed in the manuals used by gas and water engineers. It need only be noted here that iron pipes or ironwork last best when laid in a clayey soil, and worst in a porous soil. When laid in made ground,

Digitized by Google

such as that found often in the suburbs of rising towns, containing ashes and organic refuse, the life is often very short indeed, a pitting action taking place which eats the pipe in holes. This is no doubt due to local electric currents set up. In such cases extra precautions must be taken to prevent this action. The most usual way of meeting the difficulty is to cart sufficient clay from the nearest place where there is a deposit, and lay the pipes in it.

One would fancy that if there were anything better known than another in the arts it would be the behaviour of lead pipes under all ordinary circumstances; and yet it happens that this is a question into which a good deal of uncertainty has been imported by statements which have appeared within the last year or two. Lead pipes buried in the ground have for centuries been used with perfect success for the conveyance of water, and later on for the supply of gas. Hardly any excavation is made in a street without disclosing some such pipes. As a rule, they last perfectly without any protection, but it is, I believe, the universal experience of careful gas and water engineers that, particularly in some soils, and in crowded towns in the neighbourhood of sewers, it is best to protect the lead pipe by a light wood box filled up with pitch; this protects the pipe from outside influence, and in some measure from the pickaxes of workmen. On the other hand, the way lead gets eaten away when employed for sanitary purposes, particularly for soil pipes, is a well-known and never-ending theme with sanitary engineers; this action does not occur where the lead is always entirely covered by solutions containing decaying organic matter, but when it comes alternately in contact with such matter, and then with the air. Almost everyone who has lived in or had anything to do with old houses must have seen or heard of instances of action of this kind; and an extented series of speciments can be seen at the Parkes Museum of the Sanitary Institute. It is easy to imagine that lead pipes laid in a porus damp soil in the neighbourhood of leaky sewer pipes will occasionally show evidences of strong action, but because such an action may occur in a few isolated instances, where precautions have not been taken to avoid it, that is hardly sufficient for condemning the general use of lead for covering electric light cables where it is otherwise found suitable.

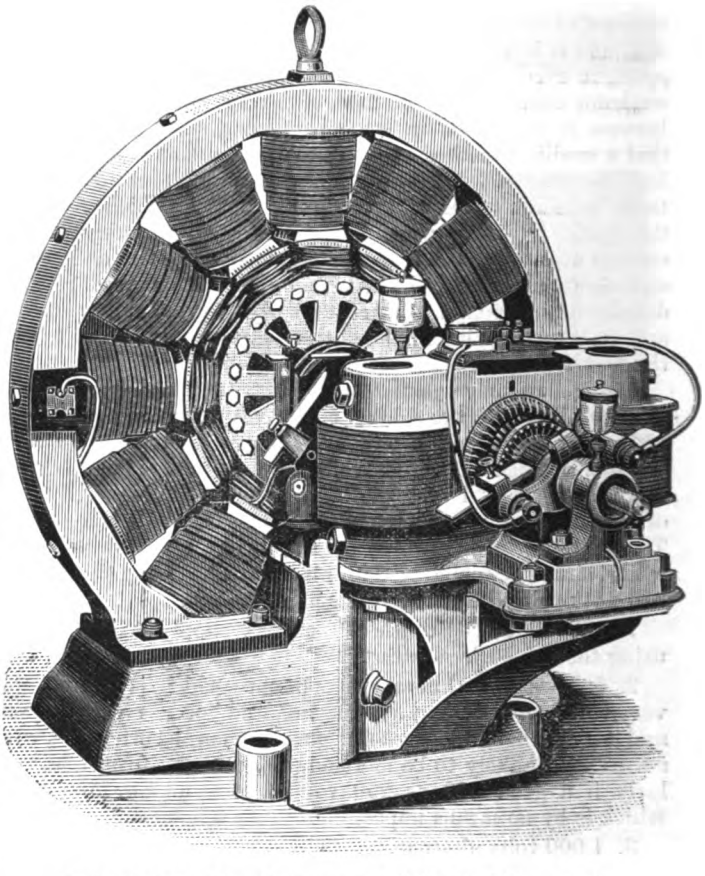
Coming now to telegraphic experience, to those interested in the various experiments tried by the early telegraph companies we would recommend a perusal of the paper read before the Institute of Electrical Engineers in May, 1887, by Mr. Thomas Fleetwood, of the General Post Office. The question is a very practical one, and there is no one who has had a longer and more practical acquaintance with it than Mr. Fleetwood, and therefore what he has to say is well worthy of the attention of those who, in a somewhat different form, have to deal with a very similar set of conditions now. Mr. Fleetwood, in his Paper, gives sufficiently fully the various contrivances used by the telegraph companies, and the reasons, where possible, of the different failures which occurred. Unfortunately, in those days they tried two new things at once, new methods of insulating wires and new forms of conduits. Consequently much of their experience is vitiated, for it is in many instances impossible to tell with certainty if the failures which occurred were due primarily to defects in the conduits or the wires, or whether the imperfection of the conduits put an undue strain on the wires. However, if these early attempts are not satisfactory on the main issues, they, at all events, have furnished a good deal of valuable information on minor points, particularly on the lasting properties of insulating and protective materials.

(*To be continued.*)

Lightning at Ben Nevis Observatory.—The Ben Nevis Observatory has for several days past been cut off from the outer world, the telegraph line having been damaged by the lightning. A lineman from Fort William made the ascent, and found all well. It appears that the flash entered the building by the wire, but that beyond a severe shock none of the inmates were injured in any way.

THE MATHER AND PLATT ALTERNATOR.

We illustrate this week a new alternator, embodying several features of interest, which is now being manufactured by Messrs. Mather and Platt, of Manchester. As is the case with most alternate-current machines in which the armature contains iron cores, the armature revolves and the magnets are fixed. The magnets are wrought iron and are arranged round the armature, exterior to it, and are attached to a massive cast-iron ring, which forms the yoke connecting the limbs. The attachment is so arranged that any of the magnet cores can be removed without disturbing the remainder or taking out the armature. The armature is constructed of two plates or discs keyed on to the shaft, between which the armature cores are held by bolts. As with the magnets, any section of the armature can be removed without disturbing the remainder. Apertures in the discs allow free ventilation in the interior of the armature cores. The magnets are excited by a "Manchester" dynamo, which is carried on a bracket bolted to the bed-plate of the alternator, the armature shafts being coupled direct.



30-Unit Mather-Platt Alternator—1,000 volts, 30 amperes.

The machines are manufactured under the patents of Drs. John and Edward Hopkinson. For working with transformers they are constructed either for 1,000 or 2,000 volts, and from 8,000 to 12,000 alternations per minute, or with a "periodicity" of from 66 to 100. The machines can be run in parallel and may be thrown into parallel working without the least danger, even when there is considerable difference between the electromotive forces at the terminals, or the machines are running at different speeds.

The machine illustrated is for an output of 1,000 volts and 30 amperes at 800 revolutions per minute. The armature resistance is 0·55 ohms, and the resistance of the magnets 2 ohms. When working with full load the current through the magnet coils is 21 amperes, showing an electrical efficiency of over 95 per cent. Messrs. Mather and Platt have already constructed several of these machines for central station work, and have a number now in course of construction.

In Fig. 7 are plotted curves deduced from the foregoing observations that show clearly the rate at which energy is given to the transformer, or that which the transformer restores to the circuit at all points of a complete alternation for the several conditions under which the transformer was operated. The curves themselves show so clearly this particular part of the performance of the transformer that nothing more need be said about them, except to give the percentages of the work given to the transformer that is restored to the circuit by it under the several foregoing conditions :—

Open circuit, 6·8 per cent.	Five lamps, ·96 per cent.
One lamp, 3·9 per cent.	Ten lamps, ·36 per cent.

The above observations and data are ample wherewith to compute the various losses of energy that take place in the transformer under the several loads and under no load, and the deduction of the corresponding efficiencies. These values have been computed, and are given in the following table.

Proper corrections have been applied for the two lamps in series with the primary of the transformer.

—	Secondary open.	One lamp.	Five lamps.	Ten lamps.
Secondary E.M.F.* Primary 1020	5·23	52·3	50·1	47·5
Primary watts	96·1	159·1	388·6	607·9
Secondary watts	0·0	64·3	300·9	525·0
Efficiency	0·0	41·1%	77·5%	86·6%
Total loss in watts	96·1	94·8	87·7	82·9
Hysteresis loss in watts	95·7	93·9	83·1	69·7
Heating loss—				
Primary watts	0·4	0·9	3·3	8·7
Secondary watts	0·0	0·0	1·3	4·5

* The values given have not been corrected for the two lamps in series with the primary for the first three conditions and the one lamp that was used for the last. With 10 lamps, where one lamp was used in the primary this correction amounts to an increase of the secondary E.M.F. of 3 per cent. On open circuit and with one lamp it is negligible, and 3 per cent. increase for five lamps. When this correction is applied, the drop of 3·5 volts obtained is what was observed by direct measurement on the secondary.

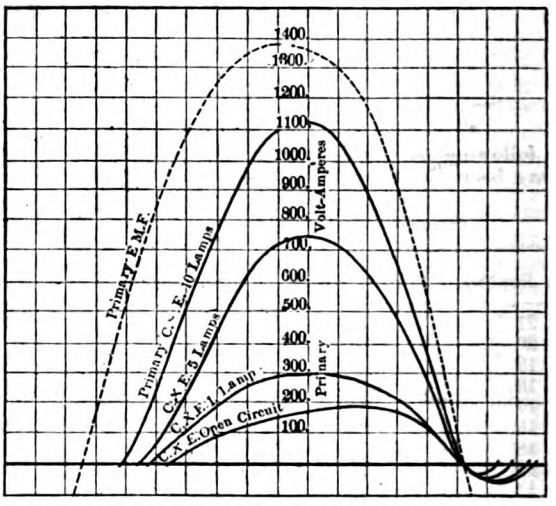

FIG. 7.

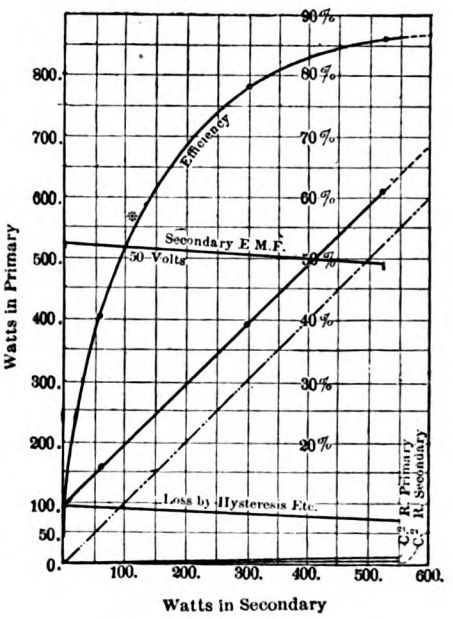

FIG. 8.

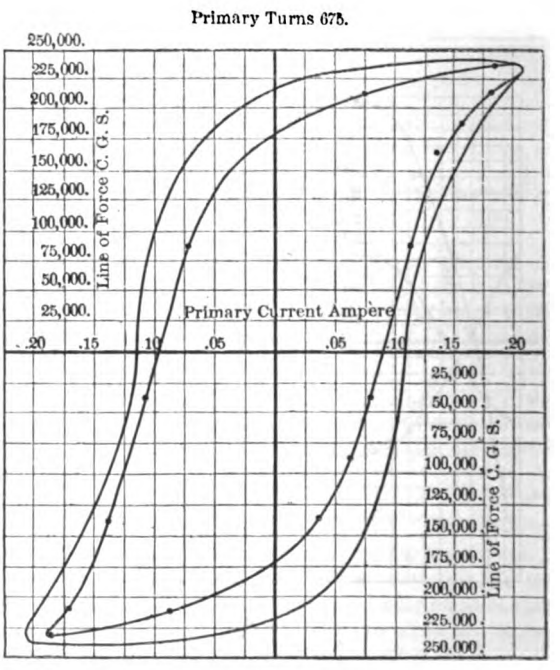

FIG. 9.

In Fig. 8 these values have been plotted to scales there indicated, and the respective curves that they determine have been drawn so that one can plainly see the exact performance of the transformer under all loads. It is interesting to note that this transformer might be load to twice its rated capacity, and the heating of the coils would still be less than that of the iron, although the heat produced by the iron grows less as the load comes on. Likewise, that its efficiency would not yet have reached its maximum, and that it would have a value of 92 per cent.

In Fig. 9 the outer curve represents the relation between the magnetising current in the primary and the degree of magnetisation for all points of a complete cycle. The values locating the curve expressing this relation were readily deduced from the observations made when the transformer was working on open circuit. In Fig. 3 the dotted curve represents the curve of primary current that would be found, should Foucault currents be known to be absent, and the relation or ampere turns and magnetisation be the same going up as coming down. Then if Foucault currents were present the dotted curve would have a component at a quarter of a period in advance. This would produce a negative lag in the dotted curve. From the position of the actual primary current it is plainly seen that but a very small component of the above nature is possible, and that the energy that is wasted by eddy currents must therefore be small. The radical departure of the primary exciting current from the approximate sinuous variation of the primary impressed E.M.F. is plainly brought out to be due to *hysteresis*. From the preceding consideration it is also evident that almost the entire advance of the exciting current, and therefore the corresponding dissipation of energy, is due to the same cause.

It was thought of much interest to see what amount of hysteresis would be indicated by carrying the transformer *slowly* through the same cycle of magnetisation that it went at the rate of 138 cycles per second when at work on the circuit with its secondary open. Accordingly, by Ewing's method, modified for the purpose by Dr. Sumpner, Mr. Merritt determined the inner curve shown in Fig. 9. We regret greatly not to have had time for a careful redetermination of this inner curve, and to carry the magnetisation to the same maxima that was done in the transformer when on the circuit. The agreement between the cards would have been more marked even than in Fig. 9.

The assumption made by Mr. Swinburne in his remarkable and valuable Paper on the "Design of Transformers" (*Proceedings* of the British Association, 1889), would therefore be fully substantiated. Mr. Mordey's experiments, in which *hysteresis* and *Foucault current* losses producing a common loss were determined, were performed by cycles of magnetisation produced by rotation, in which the degree of magnetisation did not vary in amount, but in direction, and cannot be said to throw light on the correctness of Mr. Swinburne's assumption. Some, commenting on this Paper, have used Mr. Mordey's results as evidence that these assumptions are wrong. By a knowledge, then, of the magnetic properties of the iron with which a given transformer is to be built, and the methods made use of by Mr. Swinburne, its efficiency is something that can be correctly predetermined.

The importance of making a transformer produce the same E.M.F. at the terminals of the secondary under all loads asserts itself when it is used for incandescent lighting. In the transformer under consideration, from the ratios of the primary and secondary turns, the E.M.F.s that they produced, and the variations of magnotisation that had to take place through the primary in order that the same should produce an E.M.F. equal and opposite to that of the primary impressed E.M.F., the magnetisation produced through the secondary, and the magnetisation set up about the primary in its own air space are determined. In the present transformer this "leakage" of magnetism amounted to about 1·2 per cent. When the transformer works on full load 4·5 times as much current passes through the primary, and the "leakage" of the primary in its own space is 4·5 times as much as an open circuit, and becomes 5·4 per cent. This value, together with the small drop due to the actual resistances of the transformer coils, accounts for the fall of 3·5 volts that was observed by turning on all of the ten lamps. Attention might be called to a similar "leakage" in magnetism that takes place in the secondary circuit. It is plainly brought out in Fig. 6, by the lag of secondary E.M.F. The magnetic "leakage" producing a self-induction is proportional to the secondary current. The rate of change of this quantity, then, is proportional to the E.M.F. that it produces. This E.M.F. is therefore a quarter of a period behind the secondary current and results in producing a small lag in primary and secondary currents and secondary E.M.F. Finally, there is a curious behaviour of this transformer that remains to be accounted for. This is the considerable decrease in the loss by hysteresis, as the transformer is loaded down; that is not to be accounted for by rise of temperature or the falling off of the magnetisation due to the increased "leakage" about the primary in its own air space. The following reason suggested itself to the writer why this should take place. Mechanical shock has been shown to greatly reduce loss by hysteresis when iron is passed through cycles of magnetisation. Since the currents are at all times opposite each other in the two coils of a transformer, strong repulsion occurs when these currents are at a maximum and no force is exerted when they pass through zero. So it follows that they continually keep thrusting each other apart when at work, and add to the disturbance of the laminated iron that already exists on account of its changing magnetisation. This increasing of the mechanical vibration of the iron may therefore account for the above-mentioned phenomenon. On open circuit the maximum magnetisation of the iron per square centimetre was 3,850 C.-G.-S. units. Loss by hysteresis per cycle per cubic centimetre, neglecting Foucault currents, ·046 watts at 138 reversals per second. Coercive force per centimetre of the iron, 2·76 C.-G.-S. units.

In conclusion the writer would say that the data here given show for themselves so clearly the advisability of providing some practical means for breaking the primary circuit of the transformer when not in use, that the strong advice of Mr. Swinburne in concluding his Paper need not be repeated.

MEETINGS OF SCIENTIFIC SOCIETIES, &c.

(To day) FRIDAY, January 17th.

PHYSICAL SOCIETY.

5 p.m. Papers to be read, "On a Carbon Deposit in a Blake Telephone Transmitter." By F. B. HAWES. "On Electric Splashes." By Prof. S. P. THOMPSON, D.Sc. "On Galvanometers." By Prof. W. E. AYRTON, F.R.S.; T. MATHER; and W. E. SUMPNER.

SOCIETY OF ARTS.

5 p.m. Indian Section. Paper to be read, "The India Office Records." By F. C. DANVERS.

MONDAY, January 20th.

LONDON INSTITUTION.

5 p.m. Lecture, "Coal, and what we get from it." By Prof. R. MELDOLA, F.R.S.

SOCIETY OF ARTS.

8 p.m. CANTOR LECTURE II. 1. "The Electromagnet." By Prof. S. P. THOMPSON, D.Sc.

TUESDAY, January 21st.

ROYAL INSTITUTION.

3 p.m. Lecture, "The Post-Darwinian Period." By Prof. G. J. ROMANES, F.R.S.

SOCIETY OF ARTS.

5 p.m. Foreign and Colonial Section. Paper to be read, "Tea, Coffee, and Cocoa Industries of Ceylon." By JOHN L. SHAND.

INSTITUTION OF CIVIL ENGINEERS.

8 p.m. Ordinary Meeting. Paper to be further discussed, "Recent Dock Extensions at Liverpool." By GEORGE F. LYSTER, M.Inst.C.E.

ROYAL VICTORIA HALL.

8:30 p.m. Lecture: "To Vancouvers Island and Back." By W. L. CARPENTER.

WEDNESDAY, January 22nd.

CIVIL AND MECHANICAL ENGINEERS' SOCIETY.

7 p.m. Ordinary Meeting. Paper on "The Present Aspect of Electric Lighting in London." By E. C. DE SEGUNDO, A.M.I.C.E.

SOCIETY OF ARTS.

8 p.m. Ordinary Meeting. Paper to be read, "Vision-Testing for Practical Purposes." By R. BRUDENELL CARTER, F.R.C.S.

THURSDAY, January 23rd.

ROYAL INSTITUTION.

3 p.m. Lecture: "Sculpture in Relation to the Age." By EDWIN R. MULLINS.

LONDON INSTITUTION.

6 p.m. Lecture: "On the Shapes of Leaves and Cotyledons.' By Sir JOHN LUBBOCK, F.R.S.

INSTITUTION OF ELECTRICAL ENGINEERS.

8 p.m. Ordinary Meeting. Adjourned discussion on the PRESIDENT'S Address on "Magnetism."

FRIDAY, January 24th.

INSTITUTION OF CIVIL ENGINEERS.

7:30 p.m. Students' Meeting. Paper to be read, "The Up Keep of Metalled Roads in Ceylon." By THOMAS H. CHAPMAN, Stud.Inst.C.E.

ROYAL INSTITUTION.

9 p.m. Lecture: "The Scientific Work of Joule." By Prof. DEWAR, F.R.S.

SATURDAY, January 25th.

ROYAL INSTITUTION.

3 p.m. Lecture: "The Natural History of the Horse, and of its Extinct and Existing Allies." By Prof. FLOWER F.R.S.

The Electrician.

Published every Friday. Price Fourpence; Post Free, Fourpence Halfpenny
Editorial, Publishing and Printing Offices:

No. 1, SALISBURY COURT, FLEET STREET, LONDON, E.C.

Telephone No. 2714. Telegrams: "Electrician Newspaper, London."

All Communications to be addressed to "The Electrician," *1, Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to* "The Electrician."

All letters intended for insertion in "The Electrician," *or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

"The Electrician" *is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.*

"The Electrician" *is on sale at the railway bookstalls throughout the United Kingdom on Friday morning, and can be obtained of all Booksellers and Newsvendors; or direct from the Publishing Offices as above.*

SPECIAL NOTICE.

Owing to the increase in the number of pages of "The Electrician," in order to partly cover the increased postage, we have been compelled to revise the rates for Foreign Subscriptions, which are now as follows:—

	3 months.	6 months.	12 months
For Foreign Parts and Colonies:—	s. d.	s. d.	s. d.
Within Postal Union	6 6	12 6	24 0
Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7 6	14 6	28 0
The rates for the United Kingdom remain as follows:—	5 0	10 0	19 6

TO ADVERTISERS.

"The Electrician" *offers exceptional advantages to Advertisers.* **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to the office.

Trade Advertisements *intended for the current issue must be handed in not later than First Post on Thursday morning.*

Small Prepaid Advertisements *(for Rates see page xiii.) are accepted up to 4:30 p.m. on Thursday.*

TECHNICAL PRINTING.

"The Electrician" Printing and Publishing Company (Limited) *beg to inform Electricians, Electric Light Engineers, &c., that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

"THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK.

Royal 8vo.

Early in each year is issued "The Electrician" Electrical Trades' Directory and Handbook. *The Directory was established in 1883, and the 1889 Edition consisted of more than 600 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with popularly-written Biographical Notices of the leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

The issue for 1890, which will be still further enlarged and improved, is in active preparation, and will shortly be ready. Orders should be forwarded at once to the Publishing Office, **1,** *Salisbury-court, Fleet-street, London, E.C.*

ADVANCES IN MAGNETISM.

Few of those who are outside the ranks of the technical electricians know or realise the vast advance which has been made in the last ten years in our knowledge of magnetism, and in particular of the magnetic properties of iron, steel, and nickel. The average student of physics who attends lectures by the average professor of physics, or who reads only the average text-book of physics—dating probably, on an average, ten years behind the time—is at a cruel disadvantage compared with the man who has devoted attention to the construction of dynamos or the action of transformers; for it is in the development of these practical appliances of electricity that the necessity for learning more about the magnetic qualities of materials has arisen. There is an old-fashioned science of electricity which dealt with electric fluids and action at a distance, with intensity currents and frictional machines; and a modern science of electricity which deals with potentials and resistances, with dynamos and voltmeters, with coefficients of self-induction, accumulators, and transformers. The former is the science of the schools and of the Science and Art Department; the latter is the science of the electrical engineer. So also there are two sciences of magnetism. There is the old science dealing with free magnetism and surface distribution of magnetic fluids, with magnetic moments, with torsion balances, with methods of single touch, and methods of double touch, and a hundred other relics of antiquity. And there is the new science of magnetism, which deals with permeability, hysteresis, magnetic circuits, integral magnetising forces, critical temperatures,

Digitized by Google

coefficients of leakage, and the like: in fact, with all those things which are of importance to the electrical engineer. The transition from the older to the newer science of magnetism, which has come about in so few years, may be yet far from complete; nevertheless, it makes an enormous stride forward in the handling of magnetic topics. This great advance, one portion of which formed the theme of the Presidential Address to the Institution of Electrical Engineers, has come about partly from the recognition of the principle of the magnetic circuit, partly as the result of the extended and careful experimental researches on magnetism which have been carried out in recent years. In these researches a prominent place must be assigned to the PRESIDENT himself for his careful determinations of the magnetic qualities of different brands of iron and steel; and his quite recent researches on the magnetic properties of the manganiferous and nickeliferous alloys of iron are rapidly becoming classical.

Fifty years ago the principle of the magnetic circuit very dimly suggested itself to the minds of two or three—to CUMMING, to RITCHIE, and to STURGEON; and but a few years later it assumed a more definite form in the hands of our lately deceased philosopher JOULE, who enunciated its main points. According to JOULE the induction in a magnetic circuit was proportional to its least sectional area, and the resistance to induction was proportional to the length of the magnetic circuit. To Sir WILLIAM THOMSON we owe the happy term *permeability* to denote the idea of magnetic conductivity of the material through which the magnetic lines pass. Prof. ROWLAND seems to have been the first, now nearly seventeen years ago, to point out that the law of the magnetic circuit could be expressed in exact terms similarly to the law of OHM, the number of magnetic lines flowing along the circuit being calculated from the "magnetising force of the helix" and the "resistance to lines of force" of the iron. In 1882 and 1883 a similar line was pursued by Mr. BOSANQUET in a series of magnetic researches of very great value, which somehow seem never to have received the recognition which they so thoroughly deserve, being models of careful and patient work. The more recent Paper by the PRESIDENT of the INSTITUTION of ELECTRICAL ENGINEERS in conjunction with his brother, Dr. EDWARD HOPKINSON, and that by Mr. KAPP, both dealing with the magnetic circuits of dynamo machines, are within the memory of every electrical engineer. The ten-year-long researches of Prof. EWING, though they do not directly deal with the topic of the magnetic circuit, have furnished a mass of statistical information about the properties of iron, steel, and nickel; and are, indeed, of primary importance. Prof. EWING'S work on hysteresis alone is enough to hand down his fame. Nor in this connection ought one to forget how the method of examining the magnetic properties of materials made up in the form of rings, originated by STOLETOW, has been pursued by ROWLAND, BOSANQUET, HOPKINSON, and others; nor how BIDWELL has employed the method of traction between two halves of a divided ring to measure its magnetic permeability. Prof. HUGHES has examined the influence on magnetism of torsion; WIEDEMANN has given a large number of numerical data, and a theory of the molecular actions which occur in the torsion of iron and steel under magnetisation. Sir WILLIAM THOMSON discovered the effect of stress upon the magnetic permeability of iron, and connected the observation of JOULE on the longitudinal expansion of iron during magnetisation with the diminution of its magnetisability when subjected to a longitudinal compression from without. Prof. BARRETT has observed the converse behaviour of nickel, and Mr. SHELFORD BIDWELL has pursued the matter with still higher magnetising forces, and found iron so treated to contract. Prof. EWING has made a special study of the variations of magnetic qualities of materials under varied circumstances of stress, and has greatly enriched our store of exact observations.

Dr. HOPKINSON'S address will, doubtless, stimulate an increased interest in magnetic researches: the more so as he has thrown himself into the modern modes of thought, and deliberately cut himself off from the antique notions which cling around the phrases magnetic moment, superficial density of magnetisation, and the like. The very cases chosen for discussion by Dr. HOPKINSON preclude a return to the older modes of thought. He presents to our consideration a symmetrical iron ring, overwound with a magnetising coil, and with a secondary coil for the purpose of exploring its magnetisation. With such an apparatus the magnetisation is purely internal, following a closed circuit through the substance of the ring core. Poles it has none; free surface magnetisation none; susceptibility of end surfaces to receive magnetism none; magnetic moment none. One is naturally *compelled* to regard it as constituting a magnetic circuit; to think of the magnetising force acting around it; of the resistance to magnetisation offered by the iron; of the actual resulting flow of magnetic lines through the iron core as proportional directly to the former and inversely to the latter. One falls simply and naturally into the law of the magnetic circuit: that law which, similar in all mathematical points to the great law of OHM for electric circuits, is gradually winning its way into acceptance. OHM'S law unlocked many mysteries to the electrician: the law of the magnetic circuit is similarly destined to unravel the many complications and apparent contradictions at present encumbering the science of magnetism. For the sake of the practical men, already familiar with the law of OHM, it is a pity that Dr. HOPKINSON has not frankly used the term magnetic resistance of the circuit, but has left it in its reciprocal form as conducting power. Of course, an accomplished mathematician like Dr. HOPKINSON can think things out in the reciprocals of their values with perfect readiness. Less highly-trained minds need to have new notions presented to them in more readily assimilable forms, and Dr. HOPKINSON is the last man in the world to prefer to express himself less intelligibly than he might have done. As resistance is the mere mathematical inverse of conductance, dividing by a resistance comes to identically the same thing as multiplying by a conductance. Dr. HOPKINSON does the latter, whilst the practical man is accustomed to do the former. When ten years hence, in the year 1900, the then PRESIDENT of the INSTITUTION of ELECTRICAL ENGINEERS shall come to write his Presidential Address he will be lost in wonder how it was that so late as 1890 the simple law of the magnetic-circuit—OHM'S law for magnetism—was a novelty little known and less used, too novel to be frankly accepted in a Presidential Address dealing with the magnetic properties of matter.

REVIEWS.

A Dictionary of Electrical Words, Terms, and Phrases. By E. J. HOUSTON. (The W. J. Johnston Company, New York, and "THE ELECTRICIAN" Printing and Publishing Company, London. 1889.)

This is a volume of about 650 pages, consisting of a series of short, explanatory articles on almost every electrical subject, and on many more or less closely allied ones. The articles are replete with useful information, and concisely expressed, and the errors are, on the whole, comparatively few. One of the most important of these is the definition of the C.-G.-S. unit of current given under the heading "Ampère." The unit current should be defined as a current such that if passed through a conducting wire bent into a circle of a radius of one centimetre,

Digitized by Google

each centimetre of the conductor would attract a unit magnetic pole at its centre with a force of a dyne. The definition, as given by Mr. Houston, would make the unit current $\frac{1}{2\pi}$ of its actual value. Another slip which occurs in this paragraph is the statement that an ampere per second is equal to a coulomb. There is no meaning in the expression "ampere per second," and the statement should be—an ampere is equal to a coulomb per second. Some of the definitions, as, for example, that of magnetic permeability, are extremely vague, when it would be just as easy to give exact numerical ones. The definition given of the coefficient of magnetisation is not correct, nor is that of the coefficient of self-induction, which the author confounds with the total self-induction of a circuit. In the light of recent researches a little more space might be devoted to the subject of electrical oscillations, which, moreover, can hardly be correctly described as consisting of partial intermittent discharges. The omission of all mention of the pentane standard lamp ought to be rectified in a second edition.

The work is one which will be of considerable value both to practical electricians and to students, as it contains in a condensed form a mass of information upon a great number of electrical terms and subjects, and much of this is not always readily accessible when required. If we have appeared to give prominence to the more important of the few errors and omissions which we have noticed it is because we consider the work of sufficient value and importance to make it desirable that the defects which appear in the first edition should be remedied in the succeeding ones. G. W. DE T.

Practical Electrical Notes and Definitions. By W. PERREN MAYCOCK. (London: E. and F. N. Spon.)

This is a compact little pocket-book, containing well-arranged and well-expressed information on the main points connected with the chief commercial applications of electricity. It is a book that will doubtless prove useful to that now large section of the public who find it essential to acquire a correct knowledge of the meaning of those electrical terms which are in common use. The author has for the most part confined himself with praiseworthy strictness to notes and definitions. The following paragraphs, in the prophetic vein cannot, however, be included under the heading either of notes or definitions, and might, therefore, with advantage be modified or eliminated in the next edition:—"152. The electric transmission of power is destined to become of far greater importance than all these combined. 153. Our present greatest source of energy, coal, has nowadays to be distributed broadcast over the face of the country at considerable expense before its energy can be utilised. At some future period, probably not far distant, it will be burnt at the pit's mouth, and its power electrically distributed with infinitely less loss and expense than now. 154. But this is as nothing. The time will come when the immense tidal energy all over the world will be made to do useful work, and, by the medium of electricity, furnish man with all he can require—power, heat, and light."

Examples of Lathes, Apparatus, and Work. By the Author of "Lathes and Turning." (London: E. and F. N. Spon.)

This little pamphlet of 48 pages gives much useful information with regard to the newer forms of lathe tools, more especially those required in ornamental turning. There are no fewer than 61 illustrations, of which 30 are devoted to the tools and lathes described, and the remainder illustrate specimens of the work executed by the special tools. On p. 23 we have an illustration of the "Geometric," which is a somewhat novel form of screw-cutting lathe. The term "geometric" is applied to the lathe in consequence of all its sliding movements being furnished with measuring arrangements, by which devices it is claimed that definite dimensions may be obtained with ease and certainty without the continual use of gauges and callipers. These definite movements are said to be made by making all the traversing screws of aliquot pitches of convenient numbers, and fitting the screws with small division plates. Owing to the special construction of the leading screw of this lathe, it is claimed that the compound slide-rest can be dispensed with for every kind of work, except some sorts of angular work; and the lathe is so arranged that it can be removed altogether when not in use, thus giving a clear bench. Though most of the apparatus described is more especially useful to those engaged in geometric and ornamental turning, still there are many appliances of general interest.

Magnetism and Electricity. Advanced and Honours Questions. By ANDREW JAMIESON, M.I.C.E. (London: Charles Griffin & Co.)

This is a little pamphlet of some 24 pages compiled specially for the use of those who are preparing for examinations in these subjects. The pamphlet contains all the advanced and honours theoretical questions set at the Science and Art Department's May examinations during the last eight years, as well as all the honours practical testing questions since their first institution in 1886, all the questions leading to numerical results being followed by the answers. There is no better preparation for anyone who is about to undergo the ordeal of an examination than to familiarise himself with the style of question which is in vogue by running through Papers previously set. It is needless to say that we do not suggest that this course of reading should form the chief educational pabulum of examinees, and we recommend it merely as a final dose to be taken immediately before examination.

Ordinary and Honours Questions on Electrical Engineering. By ANDREW JAMIESON, M.I.C.E. (London: Charles Griffin and Co.)

This pamphlet is similar in size and scope to that reviewed above. It contains all the ordinary and honours questions set at the City and Guilds Technological Examinations in electric lighting and transmission of power, telegraphy, and telephony, since these examinations were first instituted, as well as others by Prof. Jamieson himself.

THE INSTITUTION OF ELECTRICAL ENGINEERS.

The first meeting of the new session of the Institution of Electrical Engineers was held at the Institution of Civil Engineers on Thursday last week, Sir William Thomson, the retiring President, occupying the chair. We are indebted to *The Times* for the following report of the proceedings which took place previous to the delivery of Dr. Hopkinson's inaugural address, the continuation of which will be found in another column.

Sir WILLIAM THOMSON, before formally vacating the President's chair, delivered a short address. He pointed out that the Institution of Electrical Engineers was not, in its origin, merely a Society for electric lighting and the electric transmission of power. The great developments of recent years tended to concentrate attention on electric lighting; but it ought to be remembered that electrical engineering had originated in submarine cable enterprise. Before this electric telegraphy had hardly a better claim to be regarded as engineering than had bell-hanging. The founders of the Society were telegraphists and the great majority of them were submarine telegraphists; and all must rejoice to see that they possessed a new Member of the Council in Sir James Anderson, who had been so largely associated with cable work. It was not, perhaps, generally remembered that before the cable of 1865 a cable was laid in 1858, and in the company that laid it he and Sir John Pender were directors. Before the failure of the cable some important public messages were transmitted, notably one to countermand an order for two regiments to go from Canada to India to aid in the suppression of the mutiny. After the failure of that cable, but for the persistent, strenuous, and self-sacrificing determination of such men as Sir John (then Mr.) Pender and Mr. Cyrus Field the enterprise would have died. When, in 1865, the "Great Eastern" returned to England, having failed to pick up the broken cable, great discouragement was felt, and if Sir John Pender had not come forward to guarantee a quarter of a million of the funds required, many more years must have elapsed before the successful laying of an Atlantic cable was finally accomplished. The Institution of Electrical Engineers had a double duty—it had a duty to science and a duty to those who paid for the work. Therefore it was proper to consider how much money had been expended in various forms of electrical enterprise. In Europe, the Americas, Egypt, South Africa, Japan, India, &c., no less than 1,714,000 English miles of land telegraphs had been constructed, and the estimated value of these was £51,728,500. Of cables, 107,547 miles had been laid down by com-

Digitized by Google

panies, at a capital outlay of £36,000,000. By Government 12,523 miles of submarine cable had been laid, at a cost of £3,700,000. The figures connected with electric lighting were not so large, but were destined to be much larger. In this direction three or four millions had been spent or subscribed.

Mr. W. H. PREECE, F.R.S., then proposed, and Prof. AYRTON seconded, a vote of thanks to Sir William Thomson for his services during his year of office, and, the vote having been agreed to by acclamation, Dr. J. Hopkinson, F.R.S., the President for the new year, was installed in the chair.

THE INSTITUTION OF ELECTRICAL ENGINEERS.

DR. JOHN HOPKINSON'S PRESIDENTIAL ADDRESS.

Magnetism.

(Continued from page 247.)

I have already called emphatic attention to the fact that magnetic substances are enormously magnetic, and that non-magnetic substances are hardly at all magnetic; there is between the two classes no intermediate class. The magnetic property of iron is exceedingly easily destroyed. If iron be alloyed with 12 per cent. of manganese, the kick on the galvanometer which the material will give, if made into a ring, is only about 25 per cent. greater than is the case with the most completely non-magnetic material, instead of being some hundreds of times as great, as would be the case with iron. Further, with this manganese steel the kick on the galvanometer is strictly proportional to the magnetising current in the primary, and the material shows no signs of hysterisis. In short, all its properties would be fully accounted for if we supposed that manganese steel consisted of a perfectly non-magnetic material, with a small percentage of metallic iron mechanically admixed therewith. Thus the property of non-magnetisability of manganese steel is an excellent proof of the fact—which is also shown by the non-magnetic properties of most compounds of iron—that the property appertains to the molecule, and not to the atom; or, to put it in another way, suppose that we were to imagine manganese steel broken up into small particles, as these particles became smaller there would at length arrive a point at which the iron and the manganese would be entirely separated from each other; when this point is reached the particles of iron are non-magnetic. By the magnetic molecule of the substance we mean the smallest part which has all the magnetic properties of the mass. The magnetic molecule must be big enough to contain its proportion of manganese. In iron, then, we must have a collection of particles of such magnitude that it would be possible for manganese to enter into each of them, to constitute an element of the magnet. Manganese is, so far as I know, a non-magnetic element. Smaller proportions of manganese reduce the magnetic property in a somewhat less degree, the reduction being greater as the quantity of manganese is greater. It appeared very possible that the non-magnetic property of manganese steel was due to the coercive force being very great—that, in fact, in all experiments we were still on that part of the magnetisation curve below the rapid rise, and that if the steel were submitted to greater forces it would presently prove to be magnetic, like other kinds of steel. Prof. Ewing, however, has submitted manganese steel to very great forces indeed, and finds that its magnetism is always proportional to the magnetising force.

No single body is known having the property of capacity for magnetism in a degree which is neither very great nor very small, but intermediate between the two extremes. We can, however, mix magnetic and non-magnetic substances to form bodies apparently intermediate. It is, therefore, interesting to consider what the properties might be of such a mixture. It depends quite as much on the way in which the magnetic part is arranged in the mass, as on its actual quantity. Suppose, for example, it is arranged in threads or plates having a very long axis in the direction of the magnetising force, we may at once determine the curve of magnetisation of the mixture from that of the magnetic substance by dividing the induction for any given force in the ratio of the whole volume to the volume of magnetic substance. If, on the other hand, it is arranged with a very short axis in the direction of the force, and a long axis perpendicular thereto, we can equally construct the curve of magnetisation. This is done in Fig. 4, which shows the curve when nine-tenths of the material is highly magnetic iron arranged in the latter way, whilst the other curve of the same figure is that when one one-tenth is magnetic, but arranged in the former way. You observe how very different is the character of the curve—a difference which is reduced by the much less proportion of magnetic material in the mixture in the one case than in the other. One peculiarity of these arrangements of the two materials in relation to each other is, that the resulting material is not isotropic; that is, its properties are not the same in all directions, but depend upon the direction of the magnetising force in the material.

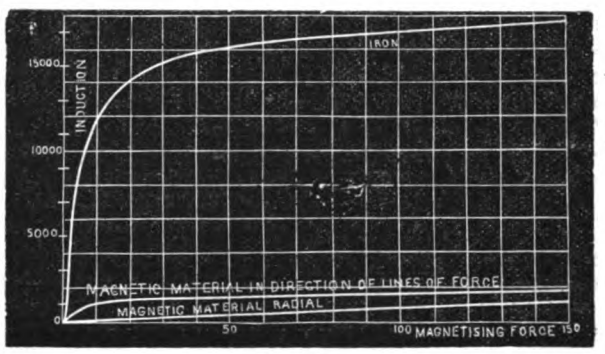

FIG. 4.

Of course, this is not at all a probable arrangement, but it is instructive in showing the character of the result as depending upon the construction of the material. Let us, however, consider the simplest isotropic arrangement; let us suppose that one material is in the form of spheres bedded in a matrix of the other: if the spheres are placed at random this is clearly an isotropic arrangement. The result is very different according as the matrix or the spheres are of the magnetic material. Suppose that the volume of the spheres is one-half of the whole volume. In Fig. 5 we have approximately the curve for iron, for a mixture of equal quantities of iron and a non-magnetic material; the spheres being non-magnetic and the matrix iron, and for a mixture, the spheres being iron, and the matrix non-magnetic. Observe the great difference. When the spheres are iron, the induction is near four times the force for all values of the force. When the matrix is iron, the induction is near $\frac{2}{3}$ths of the induction when the material is iron only.

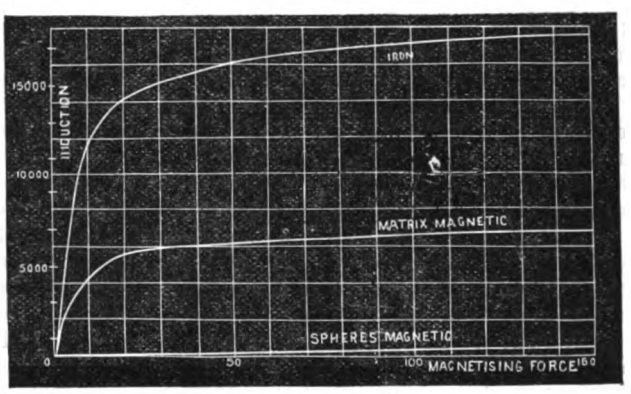

FIG. 5.

In speaking oi the properties of bodies which, like manganese steel, are slightly magnetic, it may be well here to enter a caution. But little that is instructive is to be learned by testing filings, or the like, with magnets, as these show but little difference between bodies which are slightly magnetic and those which are strongly magnetic. Suppose the filings to be spheres, in the following table are given comparative values of the forces they would experience in terms of μ, if placed in a magnetic field of given value, μ having its ordinary signification—that is, being the ratio of the kick on the galvanometer when a

Digitized by Google

ring is tried made of the material of the filing to the kick if the ring is made of a perfectly non-magnetic material :—

μ.	Attraction.	——
1	0	Non-magnetic body.
1·47	0·18	Manganese steel with 12 per cent.
3·6	1·2	Manganese steel with 9 per cent.
5	1·5	
10	2·1	
100	2·8	
1000	2·98	

Now bodies in which μ is so small as 3·6 belong distinctly to the non-magnetic class ; but the test with the magnet would very markedly distinguish them from manganese steel with 12 per cent. of manganese. The distinction, however, between $\mu = 3{\cdot}6$ and $\mu = 1{,}000$ is comparatively small ; whereas, under the conditions of experiment, μ is much more than 1,000 for most bodies of which iron is the principal constituent.

The effect of stress on the magnetic properties of iron and nickel have been studied by Sir W. Thomson. A fact interesting from a broad and general point of view is that the effects of stress are different in kind in the case of iron and nickel. In the case of iron, for small magnetising forces in the direction of the tension, tension increases the magnetisation ; for large forces, diminishes it. In the case of nickel the effect is always to diminish the magnetisation.

When one considers that the magnetic property is peculiar to three substances—that it is easily destroyed by the admixture of some foreign body, as manganese—one would naturally expect that its existence would depend also on the temperature of the body. This is found to be the case. It has long been known that iron remains magnetic to a red heat, and that then it somewhat suddenly ceases to be magnetic, and remains at a higher temperature non-magnetic. It has long been known that the same thing happens with cobalt, the temperature of change, however, being higher ; and with nickel, the temperature being lower. The magnetic characteristics of iron at a high temperature are interesting. Let us return to our ring, and let us suppose that the coils are insulated with a refractory material, such as asbestos paper, and that the ring is made of the best soft iron. We are now in a position to heat the ring to a high temperature, and to experiment upon it at high temperatures in exactly the same way as before. The temperature can be approximately determined by the resistance of one of the copper coils. Suppose, first, that the current in the primary circuit which we use for magnetising the ring is small ; that from time to time, as the ring is heated and the temperature rises, an experiment is made by reversing the current in the primary circuit, and observing the deflection of the galvanometer needle. At the ordinary temperature of the air the deflection is comparatively small ; as the temperature increases the deflection also increases, but slowly at first, when the temperature, however, reaches something like 600°C., the galvanometer deflection begins very rapidly to increase, until, with a temperature of 770°C., it attains a value of no less than 11,000 times as great as the deflection would be if the ring had been made of glass or copper, and the same exciting current had been used. Of course a direct comparison of 11,000 to 1 cannot be made : to make it we must introduce resistance into the secondary circuit when the iron is used ; and we must, in fact, make use of larger currents when copper is used. However the ratio of the induction in the case of iron to that in the case of copper, at 770°C., for small forces is no less than 11,000 to 1. Now mark what happens. The temperature rises another 15°C. ; the deflection of the needle suddenly drops to a value which we must regard as infinitesimal in comparison to that which it had at a temperature of 770°C. ; in fact, at the higher temperature of 785°C. the deflection of the galvanometer with iron is to that with copper in a ratio not exceeding that of 1·14 to 1. Here, then, we have a most remarkable fact : at a temperature of 770°C. the magnetisation of iron 11,000 times as great as that of a non-magnetic substance ; at a temperature of 785°C. iron practically non-magnetic. These changes are shown in Fig. 6. Suppose, now, that the current in the primary circuit which serves to magnetise the iron had been great instead of very small. In this case we find a very different order of phenomena. As the temperature rises the deflection on the galvanometer diminishes very slowly till a high temperature is attained ; then the rate of decrease is accelerated until, as the temperature at which

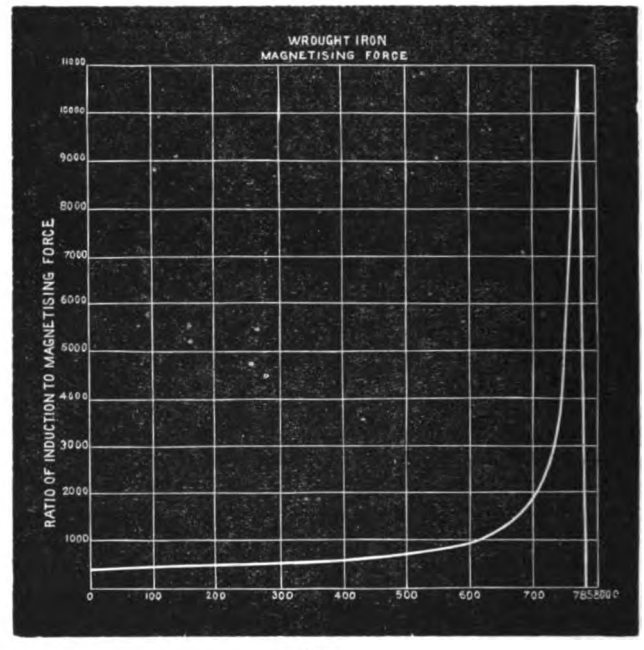

Fig. 6.

the sudden change occurred for small forces is reached, the rate of diminution becomes very rapid indeed, until, finally, the magnetism of the iron disappears at the same time as for small forces. Instead of following the magnetisation with constant

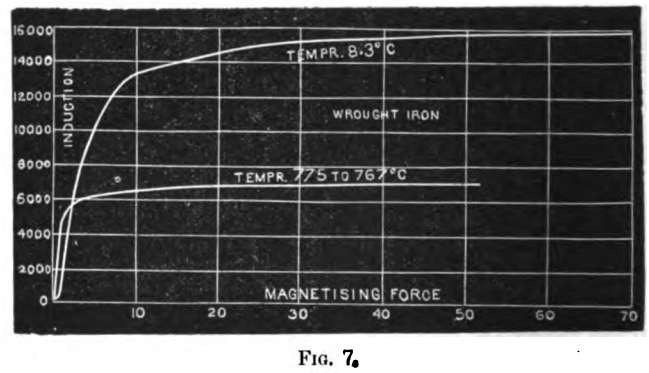

Fig. 7.

forces for varying temperatures, we may trace the curve of magnetisation for varying forces with any temperature we please. Such curves are given in Diagrams 7 and 8. In the one diagram, for the purpose of bringing out diffe-

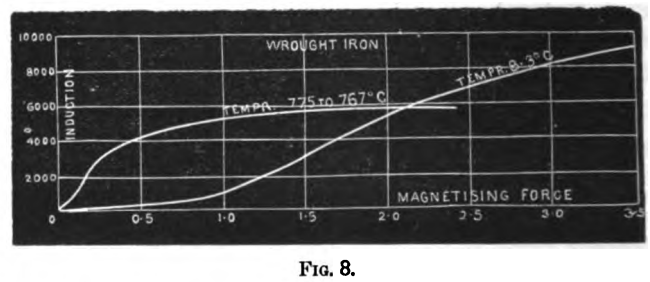

Fig. 8.

rent points in the curve, the scale of abscissæ is twenty times as great as in the other. You will observe that the effect of rise of temperature is to diminish the maximum magnetisation of which the body is capable, slowly at first, and rapidly at the end. It is also very greatly to diminish the

Digitized by Google

coercive force, and to increase the facility with which the body is magnetised. To give an idea of the magnetising forces in question, the force of Fig. 6 was 0·3; and as you see from Figs. 7 and 8, the force ranges as high as 60. Now the earth's force in these latitudes is 0·43, and the horizontal component of the earth's force is 0·18. In the field of a dynamo machine the force is often more than 7,000. In additional to the general characteristics of the curve of magnetisation, a very interesting and, as I take it, a very important fact comes out. I have already stated that if the ring be submitted to a great current in one direction, which current is afterwards gradually reduced to zero, the ring is not in its non-magnetic condition, but that it is, in fact, strongly magnetised. Suppose, now, we heat the ring, whilst under the influence of a strong magnetising current, beyond the critical temperature at which it ceases to have any magnetic properties, and that then we reduce the current to zero,

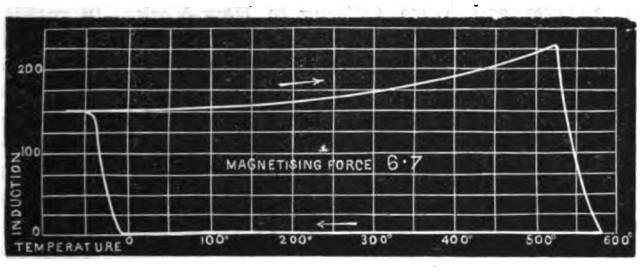

Fig. 9.

we may in this state try any experiment we please. Reversing the current on the ring, we shall find that it is in all cases non-magnetic. Suppose next that we allow the ring to cool without any current in the primary, when cold we find that the ring is magnetised; in fact, it has a distinct recollection of what had been done to it before it was heated to the temperature at which it ceased to be magnetic. When steel is tried in the same way with varying temperatures, a similar sequence of phenomena is observed; but for small forces the permeability rises to a lower maximum, and its rise is less rapid. The critical temperature at which magnetism disappears changes rapidly with the composition of the steel. For very soft charcoal iron wire the critical temperature is as high as 880° C; for hard Whitworth steel it is 690° C.

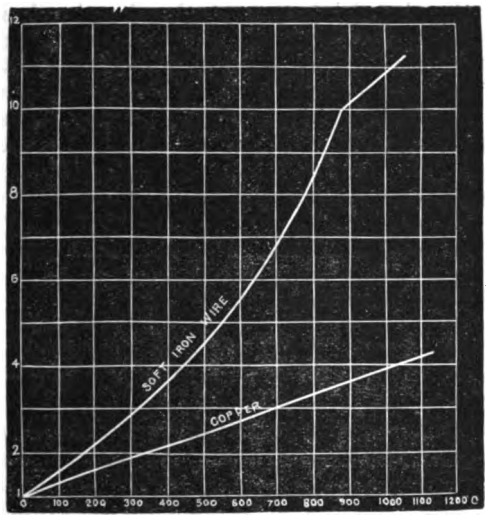

Fig. 10.

The properties of an alloy of manganese and iron are curious. More curious are those of an alloy of nickel and iron. The alloy of nickel and iron containing 25 per cent. of nickel is non-magnetic as it is sure to come from the manufacturer—that is to say, a substance compounded of two magnetic bodies is non-magnetic. Cool it, however, a little below freezing, and its properties change; it becomes very decidedly magnetic. This is perhaps not so very remarkable: the nickel steel has a low critical temperature—lower than we have observed in any other magnetisable body. But if now the cooled material be allowed to return to the ordinary temperature it is magnetic; if it be heated it is still magnetic, and remains magnetic till a temperature of 580°C is attained, when it very rapidly becomes non-magnetic, exactly as other magnetic bodies do when they pass their critical temperature. Now cool the alloy: it is non-magnetic, and remains non-magnetic till the temperature has fallen to below freezing. The history of the material is shown in Fig. 9, from which it will be seen that from – 20° C to 580° C this alloy may exist in either of two states, both quite stable—a magnetic and a non-magnetic—and that the state is determined by whether the alloy has been last cooled to – 20° C or heated to 580° C.

Sudden changes occur in other properties of iron at this very critical temperature at which its magnetism disappears. For example, take its electrical resistance. On the curve, Fig. 10, is shown the electrical resistance of iron at various temperatures, and also the electrical resistance of copper or other pure metal. Observe the difference. If the iron is heated, its resistance increases with an accelerating velocity, until, when near the critical temperature, the rate of increase is five times as much as the copper; at the critical temperature the rate suddenly changes, and it assumes a value which, as far as experiments have gone, cannot be said to differ very materially from a pure metal. The resistance of manganese steel shows no such change; its temperature coefficient constantly has the value of ·0012, which it has at the ordinary temperature of the air. The electrical resistance of nickel varies with temperature in an exactly similar manner. Again, Prof. Tait has shown that the thermo-electric properties of iron are very anomalous—that there is a sudden change at or about the temperature at which the metal becomes non-magnetic, and that before this temperature is reached the variations of thermo-electric property are quite different from a non-maguetic metal.

(*To be continued.*)

AN IMPROVED STANDARD CLARK CELL WITH LOW TEMPERATURE-COEFFICIENT.*

BY H. S. CARHART.

The best form of Clark cell hitherto made is that of Lord Rayleigh, described in the *Philosophical Transactions* for 1885. The objections to this form are that the temperature-coefficient is not the same for all cells, as is shown in Lord Rayleigh's Paper, and it is so high as to introduce a very troublesome and uncertain error, because of the difficulty of ascertaining the exact temperature of the cell; secondly, it is not so constructed mechanically as to prevent the mercury from coming into contact with the zinc when the cell is subjected to violent jars in transportation; thirdly, a great chemical defect is the facility with which local action takes place between the zinc and the mercury salt. I might add that the mercurous sulphate purchased by Lord Rayleigh evidently contained considerable salt in the mercuric form, as is shown by its turning yellow on mixing with the zinc-sulphate solution.

All these difficulties I have, at least in large measure, overcome. Respecting the materials, the greatest care is required to secure and maintain cleanliness and purity in their preparation. The mercury must be distilled *in vacuo* after being cleaned by chemical means. The zinc sulphate should be free from iron as well as other impurities. The mercurous sulphate can be made almost or quite free from the mercuric form by using plenty of mercury, keeping the temperature down to the lowest point at which action will take place, and letting the mixture of salt, acid, and metallic mercury stand for some time. I have made in this way a salt that remains white, not only when the free acid is all washed out, but when mixed with the standard zinc-sulphate solution. Further, it remains white in the cell indefinitely if it is not exposed to a bright light.

Hitherto the importance of the local action going on in a Clark cell appears not to have been appreciated. It accounts for some of the differences in temperature-coefficient, and leads to some more serious results in some cells. The zinc replaces mercury when in contact with the mercury salt. This amalgamates the zinc, producing a slight change in the E.M.F.; and then the amalgam is liable to creep up to the top of the zinc, where it attacks the solder. The copper wire is thus sometimes loosened. The zinc sulphate follows up, and the cell may be thus short-circuited by the zinc

* From the *Phil. Mag.*

Digitized by Google

and the copper wire. Upon taking down one cell, which was perhaps a year old, I found that the zinc had been removed from the rod at the surface of the liquid, and had been deposited again upon the rod at the surface of the mercury salt, in a solid frill round the zinc. The copper wire in this cell became entirely detached, partly because of the expansion upward of the marine glue, which brought a severe strain upon the wire.

The local action then increases the zinc sulphate in the cell at the expense of the mercury sulphate and amalgamates the zinc rod. I have become convinced by some experiments extending over several weeks that this substitution process goes on only when the zinc is in contact with the solid mercury salt. The mercurous sulphate is only slightly soluble in a saturated solution of zinc sulphate. I therefore prevent local action by keeping the zinc and the mercury salt out of contact. The same device operates to raise the E.M.F. about 0·4 per cent. The following table exhibits the observed and calculated values of the E.M.F. of cells No. 17, 112, 113 in terms of No. 1 (old style) at 20°C. :—

50·4	0·9949	0·9947			
52·7	0·9939	0·9940			

Cell No. 1 was always very near 20° C., and the reduction to that temperature was made by means of Lord Rayleigh's reduction-co-efficient, ·00077 per degree C.

The equation for the E.M.F., derived from the observations on No. 17, is

$$E' = E[1 - ·000387(t-15) + ·0000005(t-15)^2].$$

The calculated values for the three cells were all obtained by this formula. The change for 1°C. is, then, the following linear function of the temperature :—

$$-·000386 + ·000001(t-15).$$

The temperature-coefficient ranges from ·000361 at 0°C. to ·000376 at 25°C., and to ·000361 at 40°C. At the highest observed temperature in the preceding table it was only ·000348. The curve of E.M.F. with temperatures as abscissæ is clearly concave upward, indicating a fall in the temperature-coefficient with rise of temperature. The change is, however, so small as to be quite negligible within the range of temperature to which a normal element is subjected in practice. Lord Rayleigh's cells show a change in the temperature-coefficient directly the reverse of the above ; that is, the coefficient increases by a very appreciable quantity with rise of temperature. For his No. [36] the coefficient ranged from ·000556 at 0°C. to ·00101 at 25°C., if his equation holds true for the higher temperature.

In making comparisons of E.M.F. I have used Lord Rayleigh's method, slightly modified, by means of which a difference of one ten-thousandth part is observed directly and with the greatest ease. In fact, a difference of half that amount is easily measured. A comparison of half-a-dozen cells can be made in as many minutes without difficulty.

As to polarisation, these cells show none with external resistance greater than 30,000 ohms. At 30,000 ohms the polarisation is just discernible ; and with 10,000 ohms it amounts to only one ten-thousandth part in five minutes. This fall in E.M.F. is less than the accidental differences between different cells in general, and much smaller than the almost unavoidable errors due to ignorance of the real temperature of the cell. If the cell is not closed on less than 10,000 ohms resistance, and only for a few minutes, the polarisation may be entirely neglected.

As indicating the uniformity attained, the following relative values of the E.M.F. of six cells, only four days old, may be given :—9048, 9049, 9049, 9048, 9046, 9043. The last one was still approaching the others when last observed. Six cells of later construction gave the following relative values when less than two days old :—9182, 9182, 9182·5, 9182, 9182, 9182·5. The two sets of numbers do not represent at all the relative values of one set as compared with the other.

It will be seen from the table that Nos. 112 and 113 never differ by more than one part in ten thousand at the same temperature.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *January* 4, 1890.

The Overhead Wire Cutting in New York.—In my last letter I was able to refer to the marked change in tone on the part of the press here with regard to the question of electricity and its dangers. Now, however, that the wires in most of the streets are down, and that the thoroughfares are dark, the papers have so changed their tone that it seems hardly possible they could blow hot and cold in so short a space of time. One of the things which has brought them to their senses has undoubtedly been the outcry from the merchants and manufacturers in all parts of the city as to the damage that has been done to their business by this reckless destruction of a well-established and authorised system of supply. Altogether it is probable that for light and power the local lighting companies running circuits overhead have, or had until recently at least, 2,500 to 3,000 customers, nearly every one of whom has been affected by the cutting of the wires, and I need hardly therefore go into details to inform you as to the amount of clamour that these customers are raising as to the injury inflicted upon them in their business at this season. But for the fact that a large amount of the electric lighting in New York City is done from isolated plants, I believe that the indignation on the part of the public would have been so great as to lead to an immediate removal from office of the members of the Subway Board who are responsible for the present disgraceful state of affairs. There is now a very clear understanding on the part of the intelligent citizens as to what the whole business means, and that it is largely due to political jobbery. One hopeful feature of the situation has been to advertise the fact not appreciated by the general public, that in chopping down these wires the Board of Electrical Control were not only depriving the streets of light, but were also cutting off hundreds and hundreds of business houses and factories from light and power, to which, even with crude methods of distribution, they gave a most decided preference. Of course the companies are making as much haste as possible to get into the subways, but this work takes a long time. They also have to deal with the question of putting back their wires on streets where they have been cut, but where no subways exist. In a great many cases their wires have been cut where there has been no excuse for doing so. The local companies intend to bring a suit against the city for damage inflicted on them, and it is said that their total claims amount to nearly three million dollars. There can be no doubt that the wires have been cut in the most ruthless and wanton manner. And even where the cutting was justified by the condition of the lines, it appears that the work was done before the due legal notice had been given the companies affected. Even the wires that the companies had in the subways were rendered useless by the fact that in many cases the destruction gang cut the connections between the stations and the nearest subway terminal.

The Safety of Electric Lighting.—With regard to the alleged enormous loss of life which has led to all this furore, the Board of Coroners have just made a timely return as to the number of cases sent before them last year for investigation. It appears from these figures that 21 deaths were directly attributable to gas, 80 to being run over by vehicles, 36 to falling objects, 54 to burns and scalds, and 9 to electricity. Of these nine nearly every one, as the record shows, was directly attributable to the carelessness of the workmen and linemen employed in

Digitized by Google

connection with the supply of the current, and in but two cases, as far as I am aware, was the death that of a private citizen. In view of such a showing, one wonders how it is that it has been so easy to manufacture public sentiment against electricity, and to alarm not only New York, but pretty well the whole world besides. Attention may be drawn to the fact that over in the city of Brooklyn, where they have had a commission working in harmony with the companies, and where none of the wire used is better than the ordinary underwriters' wire, there has been no injury whatever to the public, and practically none to the *employés* and the firemen. This immunity from accident is not a plea or an excuse for underwriters' wire, which we all know to be of poor and inferior insulation for outdoor purposes; but it goes to show that where the companies are not burdened with the conditions that have been imposed upon them in New York City, they can and do render efficient service, with a minimum loss of life and property.

A Westinghouse Alternating Current Arc Lamp.—For some time past there have been reports current that it was the intention of the Westinghouse Company to introduce through the companies which it controls in New York City an alternating current arc lamp, operated through wires and cables in the subways, the object being to ensure as far as possible the safety of those coming in contact with the lights on the secondary wires. Mr. George Westinghouse, jun., has just confirmed this report, and states that the company has made great progress in the perfection of such a lamp. He says that one or two machines for the supply of current have already been constructed and that these lamps will be put into service immediately. It will be interesting thus to see a revival of an old form of arc lamp with modern modifications. If I am not mistaken, the last alternating current arc lamp seen in this country was the old Jablochkoff, operated by a company which went under the control of the United States Company, and with that company became a part of the Westinghouse system. I do not think that any of the old Jablochkoff lamps are now in use, but that every one of them found its way to the scrap heap some years ago. It will be interesting to see what form this new alternating current arc lamp takes.

Electricity in Mines.—A great deal of interest is being taken at this time in the subject of electric mining, and it is thought that 1890 will see in this country as remarkable a development in the application of electric power to mining, as was seen during 1889 in the utilisation of electric power to street railways. All the electric motor companies are beginning to adapt their apparatus to special mining purposes, and some of them have already produced not a few original applications. The *Electrical World* this week devotes a considerable portion of its space to the illustration and description of American electrical mining apparatus, and gives views of at least a dozen pieces now being brought out by the Sprague Company, the electric mining locomotive of the Thomson-Houston Company, the Sperry coal cutters, and the Jeffrey cutters and locomotives. There is other apparatus newly in the field, and several inventors are known to be at work on this class of apparatus. There are in this country about five or six thousand mines in this country, and in the case of a large number, they could be worked to much better advantage with the aid of electrical appliances, especially where water power happens to be within half-a-dozen miles. In the western mining country several applications of electricity have already been made with satisfactory results, and the mining world is well alive to the advantages offered by the new power. A large number of mining companies have for some time past had a plant for lighting, and there is not much trouble in convincing them to supplement it with an equipment of electric motors.

Wiring Recommendations of the Boston Electric Light Committee.—Since the recent fire in Boston considerable attention has been paid to the question of carrying wires into buildings, and the insulation of interior wiring. A committee recently appointed on the subject has presented a set of recommendations to the inspector of buildings in that city, and it is likely that most, if not all, of these recommendations, will go into effect. It is to be noticed that one section says: "Wires laid in plaster, cement, or other similar building material will not be allowed, no matter what insulating covering may be used. In lieu of construction by air space and non-combustible insulators, wires may be encased in insulating tubing that is impervious to moisture, will not support combustion, and of sufficient mechanical strength to protect them from injury, and such tubes may be laid side by side in plaster, cement, or other similar finish, or in any concealed space where they will not be subjected to injury, and may be supported by staples or such other means as shall not injure the tubing." It is provided also that every telephone, telegraph messenger service, or other wire, both ingoing and outgoing, shall be provided with safety fuses located as near as possible to the place where the wires enter the building, and at some point easy of access. I might add that no evidence has yet been adduced to show that the recent big fire in Boston was of electric origin.

Destruction of the Edison Station in Pearl-street.—I am sorry to have to make a note, however, of the fact that on Thursday morning of this week the old Edison station in this city down town—the first central station installed in America for the supply of incandescent lighting—was destroyed by fire. No exact account of the accident has yet been given out. It is stated that it occurred in the vicinity of the boiler room, but another account says that it was due to a short circuit outside the station which set one of the dynamos sparking violently, and ignited the oil, setting fire in turn to the old oil-soaked wooden floor. The station had been in use since 1883, and was very little like our ideal of a modern station, and about as far removed as possible in convenience, safety, and economy from the new Edison stations up town. The fire was not long in spreading through the building, and in destroying plant to the value of at least $100,000. A good deal of the load was immediately taken over by the other Edison down town station in Liberty-street. Another reason why the deprivation of light is not so severely felt is that nearly all of the very large buildings in the vicinity of the station have their own isolated plants. Funnily enough, one of the newspapers this morning gives a list of the buildings which it says have been deprived of light by the fire, and in every case but one the building has its own plant. I have cited this simply as an example of the newspaper accuracy which we have to contend with. I hear that it was recently decided by the local Edison Company, although they were well aware of the hazardous condition of their Pearl-street station, not to rebuild it at present, but to take their chance, and to push forward for the newer work in the residential portions of the city. Probably they regret this decision just at present. In some quarters there is a disposition to feel pleased to see Mr. Edison, after the recent exposition of his views on the dangers of electricity, "hoist with his own petard;" but as a rule I believe the electricians here recognise their community of interest, and are sorry to see anything occur which at this juncture can be brought up and paraded as a means of scaring the public, and spreading an idea as to the undesirability of the electric light.

Electrical Execution.—We seem to be somewhat nearer than we were to the infliction of the sentence of death by electrical execution. A decision, confirming the order which dismissed the writ of Habeas Corpus as to one of the murderers now under sentence of death has been handed down by the General Term of this State, and if nothing intervenes the execution will soon come off. The new decision admits that the sentence of electrical execution is somewhat unusual, but holds that it is not necessarily cruel, and fails to find that any facts have been established showing the new law to be unconstitutional. It says that the evidence adduced is clearly in favour of the conclusion that it is within easy reach of electrical science at this day to so generate and apply to the person of the convict a current of electricity of such nature and sufficient force as certain to produce instantaneous, and therefore painless, death. It is said that Mr. Bourke Cockran, who has been fighting this matter on behalf of the criminal in question, will carry the case to the final Court of Appeals, where he is hopeful of obtaining a reversal of the opinion. In the meantime it looks as though the criminals in this State now under sentence of capital punishment would shortly have the sentence inflicted upon them. In this view of the case, some medical and other experts, including

Digitized by Google

one whom it is unnecessary to name, have made a further trial of the apparatus installed for the purpose, and they have satisfied themselves that it will work to perfection. At this last trial they took one or two animals and shocked them to death, and then tried to resuscitate them, but in vain. The object in this experiment was to prove that there would not be any likelihood of a defeat of justice by what is known as "suspended animation." It is a great pity that the animation of our murderers cannot be suspended in the old-fashioned, ordinary way.

PARIS NOTES.

(FROM OUR CORRESPONDENT.)

January 14, 1890.

You have already, I believe, alluded on several occasions to the vigorous attack of MM. Dandeu and Naze on the Ferranti alternators at the Halles Centrales, and I think a brief account of the whole affair may not be without interest to your readers. The last move of these gentlemen has been to induce the Conseil Municipal to pass the following resolution:—The Commission Technique is invited to ascertain whether the various electric supply companies have complied with the clause in their concessions relating to the employment of foreign material, and the Commission Technique is therefore requested to visit the several generating stations and carefully inspect the whole apparatus. The members of the Commission Technique are to meet to-day, and will have to decide whether or not they shall comply with the demands of the municipal authorities and undertake the invidious task of spying.

M. Dandeu, as some of your readers may recollect, is a former workman and foreman of the late M. Gaulard. He subsequently went into partnership with M. Naze, manager of the Tours Gaulard-Gibbs transformer station, and the result of this association was the Dandeu-Naze alternator. A rough-and-ready machine was built for them by MM. Weyher et Richemond, and they then posed as candidates for the supply of dynamos to the station at the Halles Centrales. MM. Potier, Hospitalier, and Carpentier were instructed to test this new alternator, but the day originally fixed for the trial having been changed, M. Hospitalier's place was taken by M. Laffargue. At the end of an hour and a-half's run a heated bearing necessitated the stopping of the machine. It was started again, and yielded 40 amperes and 1,600 volts, but after a further run of two hours the heating of the machine brought the trial to an end. The temperature of the air space (which was 3cm. deep) was then 67° C (153° F). The result of this test was naturally an adverse report. Hence the invectives and accusations of the designers. At the present moment MM. Dandeu and Naze have fallen out, so that we may hope to hear no more of these groundless complaints.

The Municipal Station at the Halles Centrales has commenced to supply current to private consumers. The Khotinsky and Gabriel incandescent lamps are the most used, the Froger meter being employed to measure the consumption. The Société Anonyme pour le Transport de la Force (Marcel Deprez) has begun to lay the mains connecting the Rue de Bondy and Saint-Ouen stations. The method employed is the same as that in vogue on the Grande Boulevards, namely, bare copper conductors run on porcelain insulators and placed in cement conduits. A new company, the Compagnie Internationale d'Électricité, has just been formed here to work the patents of M. Pieper. Two of the main streets of Paris are shortly to be lighted by incandescent lamps and regenerative gas lamps respectively. The comparative value of the two systems will then be thoroughly investigated, and whichever proves itself the superior will be adopted for all the main thoroughfares of Paris. The Public Lighting Budget of the Conseil Municipal will thus be augmented by 150,000fr. Of this sum 50,000fr. will be devoted to improving the gas lighting and 100,000fr. to extending electric lighting.

CORRESPONDENCE.

THE "ECONOMIC RATIO" OF A TRACTION SYSTEM.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: With reference to Dr. Louis Bell's Paper on a test of the new Sprague motor, published in the last number of *The Electrician*, I should like to ask that gentleman by what process of reasoning he comes to the conclusion that, in computing the "economic ratio" of a traction system, the weight of the car should be reckoned in with the useful load. It is quite evident from the figures that he gives that he does so, and in fact I remember that in a former Paper on the same subject he defends this course by stating that the weight of the car is a necessary weight, and therefore must be included in the useful weight. Surely if the meaning of words is to go for anything, this reasoning should logically lead him in the other direction. In any case, if Dr. Bell is correct, I should like to point out to him that there is a method of increasing the economic ratio that is far simpler than seeking to improve motors, and that is by increasing the weight of his car. If he only makes this high enough he can make his economic ratio as near unity as he pleases.

Surely a fairer way would be to call the ratio of the weight of passengers to total weight the economic ratio. The figures would then be:—For a car of 3,000lb., motor 4,400lb., and passenger load 4,000lb., economic ratio = ·35. If the motor were reduced in weight to 2,500lb., the economic ratio would become ·42, and thus a decrease in motor efficiency in the ratio of 6 to 5 would still leave the ratio of receipts to working expenses the same. Still, it by no means follows that the dividend-earning capacity would be unaltered, as, of course, capital outlay is a factor in the determination of the latter.

Apologising for trespassing so much on your valuable space, for which the great attention that is now being given to electric traction in this country must be my excuse,—Yours, &c.,

18, Stanley-road, Wimbledon, H. J. S. HEATHER.
January 10, 1890.

AN ALTERNATE CURRENT "TRANSMUTER."

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Your recent illustration and description of Bernstein's continuous-current transformer, used with his constant-current system, and Prof. Robinson's recent advocacy of a similar device, induce me, a reader of your journal, to put before you a suggestion which has been long in my mind, and might be worthy of the attention of electrical engineers. It is that where the alternating current is used for distribution, customers might be provided, at their option, with a transformer (or "transmuter," for some other name would be desirable) which would convert the alternating current into a continuous one, and thus enable those who wished to do so, to charge accumulators on their premises, and do other work for which alternating currents are useless. I believe there are already alternate-current motors which, coupled to small continuous-current dynamos, would effect the object in view. Self-starting would not be a necessity, for one lamp always burning would ensure the constant running of the transformer; and if this were undesirable, or the distributing current were interrupted, the starting would be no more trouble than the turning on of gas at the main, as is done every day in some establishments. If the same idea has occurred to others, their views on the subject would, I think, be of interest to your readers.—Yours, &c., R. LANGTON COLE.

24, Finsbury-circus, E.C., January 10, 1890.

WILLIAM STURGEON.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: Will you kindly permit me to inquire through your columns whether any of your readers is cognisant of the existence of any portrait of William Sturgeon, the inventor of the electro-magnet, who died in 1850. He was long resident at Woolwich, lectured on electricity at the Adelaide Gallery and other places in London, and afterwards removed to Manchester. He founded the short-lived Electrical Society of London, and was the editor of the "Annals of Electricity." Any personal information respecting him or his writings would be very gratefully received by,—Yours, &c., SILVANUS P. THOMPSON.

20, Arundel-gardens, W.

Postal Telegraph Revenue.—The total receipts from the telegraph service from April 1, 1889, to January 11, 1890 amount to £1,820,000, against £1,640,000 for the corresponding period—an increase of £180,000.

DRAFT BOARD OF TRADE ELECTRIC LIGHT REGULATIONS.

The following is a copy of the draft regulations now being prepared by the Board of Trade for securing the safety of the public and for ensuring a proper and efficient supply of energy :—

Definitions.

In these regulations—

The expression "the undertakers" shall mean the undertakers for the purpose of the Order.

The expression "consumers' wires" shall mean any electric conductors on a consumer's premises which are connected with the service lines of the undertakers at the terminals at which energy is delivered to such consumer.

The expressions "low pressure supply," "high pressure supply," and "extra high pressure supply," are used in these regulatians with reference to the difference of electrical potential between the two conductors through which the supply of energy is given, or between any part of either conductor and the earth ; a difference of potential on any alternating current system being taken to be the equivalent of a difference of potential on a continuous current system, when it produces an equal heating effect if applied to the ends of a thin stretched wire or carbon filament ; that is to say :—

(*a*) Where the conditions of supply are such that the difference of potential, as above described, cannot at any time exceed 300 volts, if the supply be on a continuous-current system, or the equivalent of 150 volts, if the supply be on any alternating-current system, the supply shall be deemed a low-pressure supply.

(*b*) Where the conditions of supply are such that the difference of potential, as above described, may exceed the limits of a low-pressure supply but cannot exceed 3,000 volts, or the equivalent of 3,000 volts on either system, the supply shall be deemed a high-pressure supply.

(*c*) Where the conditions of the supply are such that the difference of potential, as above described, may on either system exceed 3,000 volts or the equivalent of 3,000 volts, the supply shall be deemed an extra high-pressure supply.

Mains, service lines, and other conductors and apparatus are referred to as low-pressure, high-pressure, and extra high-pressure mains, &c., according to the conditions of the supply delivered through the same or particular portions thereof.

I.—Regulations as to Safety.

General.

1. Save as hereinafter provided, the supply of energy delivered to the terminals on the consumer's premises shall be low-pressure supply.

2. A high-pressure supply shall not be delivered to the terminals on any consumer's premises except for special purposes, and with the approval of the Board of Trade, on the joint application of the consumer and the undertakers, and subject to such further regulations as the Board of Trade may from time to time prescribe.

3. An extra high-pressure supply shall not be given except to distributing stations or other premises in the sole occupation of the undertakers, and with the written consent of the Board of Trade, and subject to such conditions as the Board may prescribe.

3A. The undertakers shall provide and fix, to the satisfaction of the Local Authority, such appliances or apparatus as the Board of Trade may from time to time consider advisable, whether for safety or for the prevention of the limits of difference of potential above stated, or such other limits as may from time to time be fixed by the Board of Trade in place thereof, either generally or in particular cases, from being exceeded ; and sealed patterns of any such appliances or apparatus shall be deposited at the office of the Local Authority.

Mains and other Conductors.

4. The maximum working current in any conductor used in connection with the supply of energy shall not be sufficient to raise the temperature of the conductor in any part to such an extent as to materially alter the physical condition or specific resistance of the insulating covering, if any, or in any case to raise such temperature to a greater extent than 30 degrees of Fahrenheit's thermometer, and efficient automatic means shall be provided, which shall render it impossible for this maximum working current to be by any accident exceeded to the extent of 25 per cent., even for short intervals of time ; and special care shall be taken that the cross-sectional area and conductivity at joints are sufficient to avoid local heating, and that the joints are protected against corrosion.

5. Conductors used for a high-pressure supply shall be either separately or collectively completely enclosed in wooden pipes or casing, not less than one-quarter of an inch in thickness, placed in efficient connection with the earth, either throughout their length, or at points not separated from each other by more than 100 yards. Provided that where the conductors pass through any junction or draw box, which is not also used for low-pressure conductors, the portions so passing through such junction or draw box need not be so closed.

6. Every conductor used for a high-pressure supply must be continuously insulated with a durable and efficient material, to be approved by the Board of Trade ; and the insulation resistance of any high-pressure conductor, including joints, shall not be permitted to fall below 50 megohms per mile. This insulation must be further efficiently protected on the outside against injury or removal by abrasion. Provided that when one of the two conductors forming the line and return for any circuit or part of a circuit completely encloses the other conductor, the outer conductor, if efficiently connected to earth at the source of supply, need not be continuously insulated except to such extent as may be necessary to avoid disturbance to other lines or works.

7. Except where concentric conductors are used as provided in the preceding regulation, the insulation resistance of any complete circuit used for high-pressure supply, including all devices for producing, consuming, or measuring energy, connected to such circuit, shall be such that should any part of the circuit be put to earth, the leakage current shall not exceed $\frac{1}{15}$th of an ampere in the case of continuous currents, or $\frac{1}{10}$th of an ampere in the case of alternating currents. Every such circuit used for high-pressure supply shall be fitted with an indicating device, which shall continuously indicate if the insulation resistance of either conductor fall below the conditions required by this regulation.

8. In the case of a high-pressure supply on any alternating current system, where separately insulated conductors are used, precautions shall be taken against the discharge of electric sparks between the insulating covering of oppositely charged conductors by providing a sufficient connection of a conducting nature between these coverings throughout.

9. Where any portions of any conductors belonging to the undertakers are exposed in such a position as to be liable to be struck by lightning they shall be sufficiently protected by appliances of such pattern and construction as may from time to time be prescribed or approved by the Board of Trade.

Conduits.

10. All conduits used as receptacles for conductors shall be formed of durable material and of ample strength to resist any reasonable pressure due to heavy traffic, or other forces to which they may be subjected.

11. Where the conductors in any circuit are not sufficiently insulated, the conduit must be efficiently drained, so that no accumulation of water can take place in any part sufficient to raise the level of the water into contact with the conductors.

12. All conduits for conductors laid in streets, in which gas mains are also laid, must be thoroughly ventilated, or otherwise efficiently protected against an accumulation of gas.

13. All street boxes, manholes, junction and draw boxes must be efficiently drained and ventilated, and their covers so secured that they cannot be opened except by means of a special appliance.

Distributing Stations.

14. Distributing stations to which a high-pressure supply is given from generating stations, and from which a low-pressure supply is given to consumers, must be established on suitable premises in the sole occupation of the undertakers ; and the supply from such stations must be constantly controlled by a skilled person in the service of the undertakers, and printed directions must be conspicuously exhibited in every station, providing for the action to be taken by such person in charge in any emergency, the occurrence of which may be reasonably considered possible ; and these directions shall be submitted for the approval of the Board of Trade.

15. In every case where the supply is transformed at a distributing station, as described in the preceding regulation, means must be provided to the satisfaction of the Board of Trade, which shall render it impossible that the low-pressure mains shall be at any time charged to a dangerous difference of potential to the earth, owing to any accidental contact with the high-pressure system either within or outside the distributing station.

Consumer's Premises.

16. Where the general supply of energy is a high-pressure supply, and transforming apparatus is installed on the consumer's premises connected to the distributing mains by high-pressure service lines, and to the terminals by low-pressure service lines, the whole of the high-pressure service lines, conductors, and apparatus, including the transforming apparatus itself, so far as they shall be on the consumer's premises, shall be completely enclosed in metal casing not less than one-quarter of an inch in thickness, efficiently connected to earth, and every portion of such casing shall be securely fastened.

17. In any case where any transforming apparatus is installed on the consumer's premises, as described in the preceding regulation, means must be provided to the satisfaction of the Board of Trade, which shall render it impossible that the low-pressure service lines and consumer's wires shall be at any time charged to a dangerous difference of potential from the earth, owing to any accidental contact with the high-pressure system either within or outside the transformer.

18. All terminals, low-pressure service lines, or other apparatus between the terminals, and the transforming apparatus, or other source of supply so far as they shall be on the consumer's premises, shall be completely enclosed in insulating cases or coated with insulating material in such a manner that no part of them can be touched by any person without the removal of such case or coating ; and they shall be, wherever exposed, efficiently protected against injury to the insulation.

19. The energy shall be delivered to the consumer's premises in some manner free from the risk of causing fire on the premises in question, whether such fire should or might be originated during or in consequence of a proper or improper supply of energy or by reason of the cessation of any supply, or should or might be partly due to any defective action of the lamps, motors, storage cells, conducting wires, transformers, or other fittings connected with the terminals for the purpose of using the supply of energy.

20. If the undertakers are reasonably satisfied, after making all proper examination, by testing or otherwise, that a connection with the earth exists at some part of a circuit of such resistance as to be a source of danger, and that such connection does not exist at any part of the circuit belonging to the undertakers, then and in such case any officer appointed by the undertakers, and duly authorised by them in writing, may, for the purpose of discovering whether such connection with the earth exists at any part of a circuit within or upon any consumer's premises, at all reasonable times, after giving one hour's notice of his intention to do so, enter any

Digitized by Google

such premises and disconnect the consumer's wires from the terminals of the service lines, and may require the consumer to permit him to inspect and test the wires and fittings belonging to the consumer and forming part of the circuit.

21. If on such testing the officer discovers that a connection exists between the consumer's wires and the earth, and that such connection has an electrical resistance not exceeding 5,000 ohms, or if the consumer does not give all due facilities for such inspection and testing, the undertakers shall forthwith discontinue the supply of energy to the premises in question, giving immediate notice of such discontinuance to the consumer, and shall not recommence such supply until they are reasonably satisfied that such connection with the earth has been removed.

22. If any consumer is dissatisfied with the action of the undertakers, either in discontinuing or not recommencing the supply of energy to his premises, the wires and fittings of such consumer may, on his application, be tested for the existence of connection with the earth by an electric inspector; or if no electric inspector has been appointed, by a person appointed by the Board of Trade. For the purposes of such testing, the provisions of the order as to the testing of service lines shall, with the necessary modifications, apply to the testing by such inspector or person of the consumer's wires and fittings under these regulations.

Penalties.

23. If the undertakers make default in complying with any of the preceding regulations, they shall be liable to a penalty not exceeding £20 for every such default, and if they fail to discontinue the supply of energy to any consumer's premises upon discovery of connection with the earth, or if they recommence such supply before being reasonably satisfied that no such connection, having such electrical resistance as aforesaid exists, they shall be liable to a further penalty, not exceeding £20, for every day during which such offence continues.

The imposition of any penalty under this regulation shall not affect the liability of the undertakers in respect of any damage or injury which may be caused by reason of such default.

II.—Regulations as to Supply.

1. One week, at least, before the undertakers are ready to commence to supply energy through any feeding, charging, or distributing main or mains, they shall serve a notice upon the Local Authority of their intention to commence such supply.

2. From and after the time when the undertakers commence to supply energy through any distributing mains, they shall maintain a supply of sufficient power for the use of all the consumers for the time being entitled to be supplied from such main, and such supply shall, except so far as may be otherwise agreed upon from time to time between the local authority and the undertakers, be constantly maintained at such pressure as may be fixed under the provisions of these regulations. Provided that, for the purposes of testing, the authority by whom the electric inspector is appointed, may give permission to the undertakers to discontinue the supply at such intervals of time and for such periods as it may think expedient, and that for any other purposes connected with the efficient working of the undertaking, the undertakers may, with the permission of the Board of Trade, discontinue the supply at such intervals of time and for such periods as the Board of Trade may think expedient. Where the supply is so discontinued, notice of such discontinuance, and of the probable duration thereof, shall in every case be forthwith served upon the Local Authority

3. The system of distributing mains must be so arranged that in case it becomes necessary to stop the supply through any portion of a main for a longer period than one hour, owing to the execution of repairs, or for any other reason, the amount of supply so stopped shall in no case exceed a maximum power of 100,000 watts; and in no such case shall it be necessary to cut off the supply to more than 40 houses or tenements.

4. During the whole of a period when a supply of energy is required to be maintained by the undertakers in the distributing mains, under the order and these regulations, it shall be given at a constant pressure (in these regulations termed "the standard pressure") to be fixed as hereinafter specified. Provided that the undertakers shall be deemed to have complied with the requirements of this regulation, so long as the pressure does not at any point vary more than 3 per cent. from the corresponding standard pressure in the case of a general supply at low pressure, or 2 per cent. in the case of a general supply at high-pressure, unless changes in pressure recur so frequently as to cause unsteadiness in the supply.

5. The standard pressure may be different for different points of any pair of distributing mains but it shall not be such as to cause a difference of potential after transformation of energy if required at any pair of terminals on the consumer's premises of more than 115 volts, or the equivalent of 115 volts, or less than 45 volts, or the equivalent thereof. And in distribution, on the three-wire system, the central main shall be considered to form a pair with either of the outside mains, and similarly for multiple wire systems.

6. In the case of transformation of energy on the consumer's premises, the undertakers shall give the consumer the choice of a supply at either of two different pressures, one of which shall be approximately half the other.

7. The standard pressure shall be fixed by the undertakers for every pair of distributing mains, and notice of such amount of such standard pressure shall be given to the Local Authority before the undertakers commence to supply energy to consumers through such mains, and shall not be altered except by permission of the Local Authority, and upon such terms and conditions as the Local Authority may impose, and after public notice has been given during a period of one month, in such manner as the Local Authority may require, of the intention of the undertakers to apply for permission to alter the same. Provided that the undertakers may appeal against any decision of the Local Authority, under this regulation of the Board of Trade, whose decision shall be final.

8. The supply of energy upon any premises shall (except by agreement) be given by one or more pairs of terminals situated thereon, the respective terminals of each pair being situated at a safe and convenient distance from one another, and being in connection, respectively, with the positive and negative mains; and the undertakers shall be responsible for the maintenance of such terminals, and any other lines, fittings, and apparatus belonging to the undertakers, or under their control, upon such premises in a fit and proper condition for supplying energy.

9. The variation of pressure at the supply terminals on any consumer's premises shall not, under any conditions of supply, which the consumer is entitled to receive, nor at any time, exceed 4 per cent. from the mean pressure, whether such variation be due to the resistance of the service lines or apparatus belonging to the undertakers, or to any action or effect produced by such apparatus, for which the consumer cannot be shown to be responsible, or, partly to any variation of pressure in the distributing mains from which the supply is taken.

10. If the undertakers make default in complying with any of these regulations as to supply, they shall be liable to a penalty not exceeding £5 for every such default.

TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning.*]

Tenders Invited.—It will be seen from our advertisement columns that the Lighting Committee of the Local Board for the district of Bridlington are prepared to receive tenders for the lighting of the public streets and places within their district, by electricity or gas. Tenders must reach Mr. Charles Gray not later than Monday, January 27th.

——— The Lea Bridge, Leyton and Walthamstow Tramways Company are prepared to receive tenders for electric haulage in place of horses, provided any company or association of repute will undertake to carry out the service and guarantee due performance under proper conditions and at a fair price. Further particulars will be found in our advertisement pages, and full information can be obtained of Mr. J. B. Glenn, secretary to the company, at No. 7, Poultry, London, E.C.

The Electrical Engineering Corporation (Limited).—An amalgamation has been arranged between Messrs. J. G. Statter and Co. (Limited) and the United Electrical Engineering Company (Limited), the joint concern to be known in future as the Electrical Engineering Corporation. The Corporation has taken over the interests and responsibilities of both companies as and from the 1st inst. The Corporation is thus a manufacturing and supply undertaking, having exceptional facilities for co-operating with contractors and others in carrying out work at home and abroad in all branches of the electrical industry. The Alliance Engineering Works at West Drayton are within fifteen miles of London, on the main line of the Great Western Railway, and have a dock and wharf upon the Grand Junction Canal, the works are already extensive and complete, and when the extensions now in progress have been completed they will cover about four acres of ground, and contain some of the largest machine tools employed in the trade. The situation of the works is favourable for the economical despatch of material both for home and foreign use. The Albert Works (36, Albert-embankment, S.E.) are devoted to the manufacture of switch, safety junction, and regulator gear, together with other fittings and accessories suitable for a wide range of electrical work. The London offices are centrally situated, being at Prince's Mansions, 68, Victoria-street. The managing directors of the corporation are Messrs. J. G. Statter, Edward Manville, and William L. Madgen.

Dissolution of Partnership, &c.—We have received from Messrs. Gent and Co., of Leicester, the following notice:—"We desire to inform you that the partnership hitherto existing between Messrs. J. T. Gent and H. G. Ellery has this day been dissolved by mutual consent. All debts will be received and paid by Mr. J. T. Gent." This notice is accompanied by the following, signed by Mr. J. T. Gent:—"I have pleasure in informing you that I have this day taken into partnership Mr. A. W. Staveley and Mr. I. H. Parsons, and that the business will be continued under the usual style of Gent and Co., Electricians."

The Electric Welding Syndicate.—Permission to view the electric welding process may be obtained on application to Mr. William Bevan, secretary *pro tem.*

Swinburne and Co.—This firm report that they have already received orders for some of their new open-circuit or "Hedgehog" transformers for town installation work. Messrs. Swinburne are sanguine as to the success of this transformer, and are making preparations to turn them out on a large scale. They intend shortly to introduce a new non-induction watt-meter for alternating or con-

Digitized by Google

tinuous currents. The "Hedgehog" transformer is made to a number of stock sizes, from 25 30-watt lamps to 1,000 30-watt lamps, and other sizes can be made to order. Advantages claimed are that the transformer is perfectly insulated, and does not get hot.

THE ELECTRIC CONSTRUCTION CORPORATION.—We have received some neatly-printed sheets of price lists of Elwell-Parker 50-volt, 60-volt, 80-volt, 100-volt, and 135-volt continuous-current dynamos, of accumulators, glass insulators, and hydrometers. The tables given show at a glance the electrical output, dimensions, and prices of each of the above dynamos, as well as the approximate speeds in revolutions per minute. These sheets are in a very handy form.

MESSRS. FOWLER, LANCASTER, AND CO. (LIMITED).—We have received from this firm a copy of their new catalogue just issued, which contains a number of illustrations of batteries, bells, indicators, fire alarm telegraphs, time controllers, telegraph instruments, telephones, lightning conductors, switches and keys, electric pulls and pushes, burglar alarms, electro-medical appliances, small dynamos and motors, electric gas lighters, testing apparatus, lineman's tools, insulators, compasses, barometers, hydrometers, thermometers, contact pillars, terminals, nuts, and connectors. These illustrations are accompanied by full descriptions as to price, &c. Some interesting notes are given on electrical bell communication and instructions for their proper fixing. The catalogue is neatly got up, has a full index, and consists in all of 60 quarto pages. Messrs. Fowler, Lancaster and Co. announce that other catalogues are now in the press dealing with every electrical requisite for contractors, &c., &c.

ELECTRIC LIGHT ENGINES.—We have received the engineering section catalogue just issued by Messrs. Ransomes, Sims, and Jefferies. It consists of 80 quarto pages, fully illustrating the well-known types of engines manufactured by this firm. On pages 8 and 10 are shown new designs of portable engines with one cylinder, in the first of which the guide bars, of the circular type, are formed in one casting of the cylinder, and in the second are embodied all recent improvements. To meet a growing demand, Messrs. Ransomes, Sims, and Jefferies have adapted the boilers of their portable engines so that oil can be used as readily as any other fuel. The illustration on page 13 of the catalogue shows the general arrangement of a portable steam engine fitted with the petroleum burning apparatus. The apparatus consists of a supply tank for holding a certain quantity of petroleum, which is placed above and at the side of the fire-box of the engine, and an arrangement of pipes for conducting the petroleum and super-heated steam to the special burner in the furnace. The fire-box, which is of extra large dimensions, can be readily changed by the addition of other parts from a petroleum-burning furnace to either a straw, wood, or coal burning furnace. An example of the straw-burning engine is shown on page 14 in section and perspective. On pages 18 and 20 are shown examples of high-pressure engines specially recommended for electric lighting, being fitted with the firm's patent automatic governor expansion gear. On page 28 an illustration appears of the patent gear with which all engines built by this firm specially for electric lighting purposes are fitted, an illustrated description of which recently appeared in *The Electrician*. The catalogue contains a large number of illustrations and descriptions of all kinds of engines, all of which are fitted with the most recent improvements. The concluding illustration is a fine view of the company's large works at Ipswich, covering 13 acres, and employing between 1,200 and 1,400 hands.

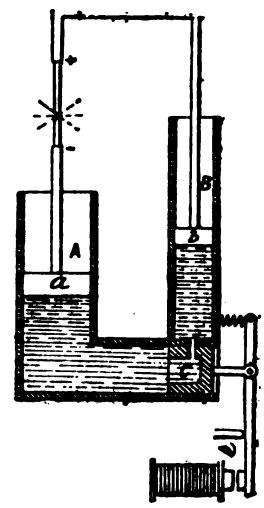
THE STOCHER-SEDLACZEK ARC LAMP.*

The principle of the Stocher-Sedlaczek arc lamp is the same as that of MM. Lacassagne and Thiers described in *The Electrician* of November 15th; but the liquid employed is glycerine instead of mercury. In the accompanying figure we have a diagrammatical representation of the apparatus.

The two vertical cylinders A and B are in communication with each other through a horizontal cylinder. The piston *a* carries the negative carbon holder, the piston *b* the positive carbon holder; the function of the third piston *c* being to establish and interrupt communication between the cylinders A and B. An electro-magnet placed in the main circuit, by influencing an armature connected to the piston *c*, actuates the latter. When the action of the electro-magnet weakens, a spring causes the armature, and consequently the piston *c*, to move in the reverse direction.



The Stocher-Sedlaczek Arc Lamp.

On the circuit being closed, the armature is attracted, and the piston *c* moves from left to right, cutting off communication between A and B, and causing piston *a* to fall and strike the arc. When the current weakens by reason of the lengthening of the arc, the spring overcomes the attraction of the electro-magnet upon its armature, and the piston *c* is moved from right to left, communication between the two vertical cylinders is restored, liquid flows in from B to A, and the arc is reduced to its normal dimensions. The diameters of the cylinders A and B are proportioned so as to give the arc a fixed position. This lamp can be employed with advantage on locomotives, the light remaining very steady even when exposed to severe oscillation.

COMPANIES' MEETINGS & REPORTS.

The Eastern Telegraph Company (Limited).

The 35th half-yearly ordinary general meeting of this Company was held yesterday (Thursday) at Winchester House, Old Broad-street, E.C., under the presidency of Sir John Pender, K.C.M.G.

The SECRETARY (Mr. George Draper) having read the notice calling the meeting, the following report of the Directors was taken as read:—

1. These accounts and balance sheet are for the six months ended September 30, 1889.

2. The revenue for the period amounted to £351,014. 19s. 4d., from which are deducted £87,730. 15s. 9d. for the ordinary expenses and £49,634. 11s. 6d. for expenditure relating to repairs and renewals of cables, &c., during the half-year. After providing £4,724. 10s. 11d. for income-tax, there remains a balance of £208,925. 1s. 2d., to which is added £974. 15s. 6d. brought from the preceding half-year, making a total available balance of £209,899. 16s. 8d.

3. From this balance there have been paid—

Interest on Debentures and Debenture Stock	£28,274	12	7
Dividend on Preference shares	20,474	2	8
Two interim dividends of 2s. 6d. per share each on ordinary shares	100,000	0	0
	£148,748	15	3

Leaving a balance of £61,151. 1s. 5d., which is carried forward to the next account.

* Translated from M. Hippolyte Fontaine's "Éclairage à l'Électricité," by kind permission of the Author.

Digitized by Google

4. The revenue includes £37,318. 4s. 11d. dividend for the half-year upon the Company's shares in the Eastern and South African, the Black Sea, and the Direct Spanish Telegraph Companies. The cables of these Companies are in good working order.

5. All the sections of the Company's cables, without exception, are in good working order.

6. During the past six months, in consequence of the political disturbances in the Island of Crete, the telegraph lines on the island were interrupted.

The Directors applied to the Turkish Government for permission to lay a duplicate cable between Canea and Candia, a distance of 70 knots, which was required for the increased amount of traffic thrown upon the Company's cable by the interruption to the land lines. As it was of the greatest importance to the Turkish Government that telegraphic communication should be efficiently maintained between the Porte and Crete, the Firman was at once granted and the cable laid, the cost of which has been charged to the reserve fund.

To meet the requirements of the increased traffic new cables have been laid connecting Patras with Corinth (75 knots) and Piræus with Kalamaki in the Gulf of Athens (31 knots). The cost of these cables has also been charged to the reserve fund, as well as that of the Perim-Oboch cable referred to in the last report. The laying of this cable was completed on July 17th

7. In accordance with the Articles of Association, two of the Directors, George Garden Nicol, Esq., and John Denison Pender, Esq., retire by rotation at this meeting, and, being eligible, offer themselves for re-election.

8. The auditors, Mr. Henry Dever and Messrs. Welton, Jones, and Co. retire, and offer themselves for re-election.

The CHAIRMAN said that the gross revenue for the half-year ended September 30th had been £351,014, or an increase of £40,910 compared with the corresponding period of the previous year. That was a very handsome increase, and about £29,000 was derived from messages and £12,000 from additional dividend on the Company's increased holding in the Eastern and South African Company. Those figures showed that the revenue for the half-year had been exceptional, and they hoped that the improvement would continue. He might remind them of what he had frequently said before, that the revenue of the Company depended in a great measure on the state of the trade of the country. As he had frequently said, the submarine telegraph system was about the best barometer of trade, and while they all admitted that commercial prosperity had prevailed throughout the world, the result of the past half-year's working showed that the Company had participated in the improved state of things. The greater part of the increase had been caused by the development of business in South Africa, but it was pleasing to note that with one exception — namely, India — an increase had taken place in all classes of their traffic owing to the general improvement of trade both at home and abroad. The general prosperity of the country affected almost every article which was dealt in, and all the materials required to make cables had enormously increased in price. The total working expenses of the half-year had been £87,730, being an increase of £4,398. The general expenses in London had been £566 more, owing to the steady increase of their business requiring more hands, additional accommodation, &c. The working expenses at the stations had been £64,712, being an increase of £4,750 over those of the same half of 1888. There had been an increase of 40 in the number of the staff, and they had given increases of salary to their principal *employés*, more particularly the superintendents abroad. Repairs to cables had cost £49,634, or £6,569 more, full details of which would be found in Abstract "C" of the accounts, which was really a very interesting abstract. It showed the expenses of their steamers and also the improvements which were being made in their property. The steamers moved about from place to place conducting the repairs in the most silent way possible, and their system was now almost as perfect as it was possible to make it. He had often stated that a single line of telegraph was not to be relied on. Unless they had a duplicate line they could not give that confidence required by merchants, who depended on the cables for carrying through their large mercantile operations. Only the other day the submarine telegraph system was regarded as the great feature of the age in politics, but he held that it was a still greater feature now in connection with commerce. They did not profess to go in for extreme dividends, but they had endeavoured to put by such an amount as would secure not only the present position, but build up great security for the future; and as they strengthened their foundations so they would be able in the future, he hoped, to increase their dividend. They carried forward to the credit of next account over £61,000. If they were as successful in the current half-year as they had been in the six months under review, the shareholders might expect a satisfactory bonus. Africa was now being opened up, and last year they completed a circuit of the whole of that dark continent, and that was the greatest operation which had ever been carried out in connection with submarine telegraphs, involving, as he had said at the last meeting, something like 17,000 miles of cable. While other countries were striving hard to get a footing in Africa, this Company were the pioneers, and had put themselves in such a position that at every point of the seaboard they were in communication with the old country. The English-speaking people, it might be said, had developed Africa up to the present point, and as long as the English tongue and the enterprise which followed it continued, they had a wide field for development in Africa. Portugal had behaved generously to the Company. If that country had shown the same enterprise as England, it would now have very large claims in Africa; but having held a position for a very long time there, they had allowed matters to remain dormant. However, as he had said, Portugal had helped them, France had to some extent, and so had Spain; but, curiously enough, the only country that had not assisted them in any way was Germany. Germany was now trying to get a hold in that country, but they found that they could not do so without doing something for submarine telegraphs. Inquiries were now being made on the part of Germany in connection with that matter, and he hoped that when they next met he would be able to state that Germany was now taking her part in connection with submarine telegraphy, which was doing so much for the good of the whole world. Their policy had been as far as possible to follow the trade and flag of England. Africa was now in a state of transition. There were two imperial British companies there in the hands of bold, intelligent and large-minded men, and there was no doubt there would be rapid development there. Without hesitation, therefore, the Company had laid down (he believed the cable was completed to-day) a cable from Zanzibar to Mombassa, the head-quarters of the Imperial East African Company, which was working under a royal charter. That section would put them in communication with the whole of the civilised world. To borrow a phrase, he might say they were on very friendly relations with every Government in the world. Recently the Emperor of Morocco visited Tangiers, where the Company had landed a cable, and His Majesty was so pleased with what he saw that he presented them with a site to build an office upon, as an evidence of goodwill towards the Company. The Sultan of Zanzibar had also given them a site and a house for their station, as well as every possible facility. Two days ago they had concluded with France agreements which would extend over the next twenty years, thus renewing agreements which had already existed for some years, and which would give the Company a very strong hold indeed upon the Mediterranean system of telegraphs. They wanted the telegraph system to have, as far as possible, an international character. He found that the different countries were by degrees recognising this policy, and that, on the whole, they were very friendly towards the Company. A letter had been addressed to Sir James Anderson by a shareholder, who wrote to ask whether a telegraph conference was to be held in Paris, and whether it was likely to reduce the

Company's tariffs, and consequently interfere with their dividends. In reply to that he had to state that a conference would be held in Paris, as it was held in Berlin five years ago; but their position was so strong, and they were so useful to all nations, that he could not see how they would interfere with, or do any serious harm to, the Company. There was not a Power in Europe whose land telegraph system was returning a profit, and it would be very hard for the conference to reduce the rates of the Company in any unfair way, simply because they could reduce their own rates as they pleased out of the public money. Whatever concessions they might make he believed they would be in such a direction that they would produce an increased traffic, by which their revenues would not lose. That was the policy they intended to pursue at the conference. They had now a little difference of opinion in regard to Egypt, whither he was proceeding in a few days, and he hoped his visit would be instrumental in settling the little misunderstanding that existed. He knew that they would be fighting with right on their side. He concluded by moving the adoption of the report and accounts.

The VICE-CHAIRMAN (the Marquis of Tweeddale) seconded the resolution, which was carried unanimously.

On the motion of the CHAIRMAN, seconded by Sir JAMES ANDERSAN, Mr. Geo. Garden Nicol was re-elected to his seat at the Board, as was also Mr. J. D. Pender.

The Auditors, Mr. Henry Dever and Messrs. Welton, Jones, and Co., were re-appointed, and the meeting closed with a vote of thanks to the Chairman and Directors.

[*We shall publish a full report of this meeting in our next issue.*]

Direct United States Cable Company (Limited).

The following is the report of the Directors for the six months ended December 31, 1889, to be presented at the twenty-fifth ordinary general meeting of the Company, to be held at Winchester House, 50, Old Broad-street, E.C., on Friday, January 17th, at two p.m.:—

2. The revenue for the half-year (still subject to revision), after deducting out-payments, amounted to £42,356. 12. 1d. against £34,188 (after similar deductions) for the corresponding period of 1888, being a difference of £8,168. 12s. 1d. in favour of the half-year under review, owing to the operation of the 1s. tariff throughout the whole of this period, as compared with tariffs of 6d. for two months, and 1s. for four months, in the corresponding period of the previous year.

3. The working and other expenses for the same period, including income-tax, but exclusive of cost of repairs of cable, amounted to £15,509. 7s. 8d., leaving a balance of £26,847. 6s. 5d. as the net profit of the half-year, making with £2,719. 2s. 11d. brought forward from the previous half-year, a total of £29,566. 9s. 4d. For the corresponding half-year of 1888 the working expenses and other payments amounted to £16,475. 6s. 9d.

4. Interim dividends of 3s. 6d. per share for the quarter ended September 30, 1889 (paid October 24, 1889), and of 3s. 6d. per share for the quarter ended December 31, 1889 (payable January 24, 1890), together amounting to £21,248. 10s., have been declared, and the balance of £8,317. 19s. 4d. on the revenue account has been carried forward.

5. An interruption of the main cable occurred on October 9th last, in the neighbourhood of the Green Bank, and was repaired on November 2nd. The cable was found to have been broken by a vessel's anchor. On November 9th, in a position near the previous break, the cable was again interrupted for the removal of a fault which interfered with efficient working. The fault was successfully cut out, and communication restored, on November 12th. The cost of these repairing operations, including spare cable used, amounting to £4,119. 14s., has been charged to the reserve fund account, as usual.

6. In the matter of the action of the Anglo-American Telegraph Company *v.* Cie. Française du Télégraphe de Paris à New York, the appeal to the Council of State mentioned in the last report is still pending.

NEW COMPANIES REGISTERED.

ARGENTINE INTER-PROVINCIAL RAILWAY COMPANY (LIMITED).—Registered by Ashurst, Morris, Crisp, and Co., 6, Old Jewry, E.C., with a capital of £1,200,000 in £100 shares. Object, to acquire, construct, complete and equip, maintain, prolong, and work railways and their appurtenances, tramways, lines of telegraph, telephones, or other means of communication in the Argentine Republic. There shall not be less than three nor more than seven directors; the first to be appointed by the subscribers to the Memorandum of Association. Qualification, £500. Remuneration, £3,500, divisible.

FOWLER, LANCASTER AND COMPANY.—This company was registered January 8th, by Pyke and Minchin, 2, Metal Exchange-buildings. Objects: To carry on the business of electrical engineers, manufacturers, and contractors in the United Kingdom or elsewhere, and to light thoroughfares and public and private buildings, adopting therefor an agreement, the particulars of which are not specified in articles, dated January 4, 1890, and made with George Vaughan Fowler and Edward William Lancaster, electrical engineers at Birmingham. Capital, £22,000, in £10 shares, of which 20 are deferred shares. Subscribers of one share each are:

Arthur Mackenzie, agent, Temple-chambers, Temple-avenue.
William Marcus Pyke, solicitor, 2, Metal Exchange-buildings.
Albert Edmund Shill, architect, 30, Dayton-grove, Peckham.
Herbert Lenty Collins, clerk, 67, Lombard-street.
Charles William Rawlinson, solicitor, 11, Lincoln's Inn-fields.
Reginald William Bonser, clerk, same address.
Charles A. Elgood, solicitor, 48, Lincoln's Inn-fields.

One vote for every five shares, but maximum number of votes not to exceed 20. First directors (two to four) to be nominated by above-named subscribers, who act *ad interim*. George Vaughan Fowler and Edward William Lancaster are to be first managing directors, with all rights and powers of directors reserved in the afore-mentioned agreement. Qualifications of directors 50 shares. Remuneration of others than managing directors £100 per annum each (chairman £150 per annum), and in addition 10 per cent. on profits after 10 per cent. dividend to be divisible. Borrowing powers are not restricted.

NEW ASBESTOS COMPANY (LIMITED).—Registered by Michael Abrahams, Sons, and Co., 8, Old Jewry, E.C., with a capital of £120,000, divided into 30,000 shares of £4 each. Object, to acquire and take over upon the terms of an agreement, dated August 20, 1889, and expressed to be made between the Société Française des Amiantes of the one part, and Wm. McDonell, as trustee for the New Asbestos Company (Limited) of the other part, or any modification that may be agreed to, the assets and good will of the business of asbestos manufacturers and merchants carried on by the said Société at Tarascon, in France and elsewhere, including certain asbestos properties situate in France and in Italy.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended January 10th amounted to £1,728.

EASTERN EXTENSION COMPANY.—This company notify that the interest on their Six per Cent. Debentures, due February 1st next, will be paid on and after that date at the Consolidated Bank, 52, Threadneedle-street, E.C.

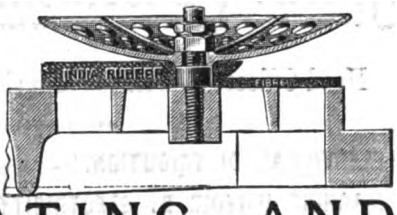
ELMORE'S PATENT COPPER DEPOSITING COMPANY (LIMITED).—Considerable business has lately been doing on the Stock Exchange in the shares of this Company. Quite recently the price of the £2 shares rose to 8⅝, but owing to rumours that the works had started and had failed, the shares fell to below 7, but have now risen to 7¼—⅜. The rumours above referred to are, we are informed, incorrect, as the works have not yet started, but are upon the point of so doing, and we feel sure that, with the assistance of the eminent electrical firm who are associated with the process, success will ensue.

NOTTING HILL ELECTRIC LIGHTING COMPANY (LIMITED).—Letters of allotment in this Company have been posted.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended January 10th, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited), were £3,434.

NEW VALVE

No Rubber, Percha, or Leather.



One-half the price of Rubber or Metal.

FOR CIRCULATING AND AIR PUMPS.

Unaffected by any Lubricating Oils. Does not Expand in diameter. Feed Water may be worked at any temperature Suitable for any shaped guards. Only one quality manufactured.

"12, John-street, Sunderland, 26th Sept. 1885.

"DEAR SIRS,—In reply to your letter of the 25th inst., the Valves I got from you have done their work well, and ARE AN UNQUALIFIED SUCCESS. I will continue to get them from you as required.—Yours faithfully, JAMES WESTOLL."

For further Testimony and Prices, apply to MOSSES & MITCHELL, 68-71, Chiswell Street, London.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 610.—Vol. XXIV. FRIDAY, JANUARY 24, 1890. Price Fourpence.

NOTES.

As we have previously announced, the Royal Society resolved in November last to raise a fund for establishing a memorial of an international character commemorative of the life work of Joule. This memorial it has been decided shall have for its object the encouragement of research in physical science, as well as the erection of a tablet or bust in London. It is unnecessary to insist on the world-wide importance of the discovery of the law of the conservation of energy, or to again point out the vast field covered by Joule's researches and the marvellous accuracy of his results. Electricians, we feel confident, will not be backward in contributing towards a fund to do honour to his memory.

In the suggestive Paper by Mr. Albion T. Snell on "The Distribution of Electrical Energy over Extended Areas in Mines," which will be found in another column, the employment of alternate-current motors on a commercial scale is placed, not without reason, somewhat *in futuro*. It is interesting to note in this connection that our New York correspondent reports this week that the Hercules Mining Machine Company, of Pittsburgh, have given a large order to the Westinghouse Company for Tesla motors to operate their coal-mining machines. The result of this venture will be watched with considerable interest by electrical engineers in this country, who have not up to the present been over-favourably impressed by the performances of this motor so far as they have been made public.

It will be seen also by our New York letter that the telephone companies are in many cases offering a vigorous opposition to the introduction of electric traction. This is not surprising, since an electric railway with an earth return must be a peculiarly severe trial to the somewhat delicate constitution of a telephone system.

Duplex telephony has hitherto not been actually brought into practical operation, although it has been known to be theoretically possible. The recent researches, however, of Dr. Rosebrugh, of Toronto, which we describe in another column, appear to have led him to several practical suggestions for the use of telephone lines to carry more than one message at one time. Some of these suggestions, though they increase the carrying capacity of the lines, are sesqui-plex rather than duplex. Dr, Rosebrugh has come out victorious in the interference case in the United States Patent Office, which has long been pending on this invention between himself and the electricians of the Western Union Telegraph Company.

When is the microphone interference case in the United States Patent Office to be settled? For twelve years the ball has been kept rolling between Berliner and Edison, both of whom claim priority. No doubt delay is to the interest of the rival parties, since the patent, *when issued*, will date from the day of issue. Our American cousins will have to serve a seventeen years' monopoly from that date for an invention which has already been tied up for twelve years, and which ought in five years to be free. Yet they call the States a free country!

Prof. Righi has been extending his researches on the action of ultra-violet rays in augmenting the potential of a body placed in their path. The theory is that under the influence of such radiation the gaseous particles near the body become charged negatively, and are transported along the lines of electric force. The loss of the negative electricity causes the body to have a higher positive potential, and this process of molecular convection goes on until the attraction between the negatively charged particles and the positively charged body prevents further action. The convection ceases when the electric density attains a certain maximum, for this determines the magnitude of the electric force. It follows that spheres of the same material become charged to potentials proportional to their radii, and that a plate becomes charged proportional to its distance from an earth plate placed parallel to it. These results Righi proves by careful measurements with a Mascart electrometer. The light employed was a special zinc burner rich in ultra-violet rays. The effect varies with the nature of the light, and also with the substance examined. The order of the metals is about the same as that in which a negative charge is lost under the action of ultra-violet light. The augmentation of potential is greater the higher the temperature. The effect is increased in a very marked degree by rarefying the air, probably because of the greater freedom of motion of the gaseous molecules.

Among other things the research suggests a new method of measuring the potential difference of contact of dissimilar substances, but, like every other method, it is subject to many points of criticism. Another result of Prof. Righi's experiments is a means of producing electric figures of quite a novel kind

Digitized by Google

by the action of ultra-violet rays on the surface of metals. It seems probable that under the action of these rays metals partially lose the gaseous film with which they are surrounded, although this film is not necessarily the source of the molecular convection. These experiments offer an explanation of the well-known fact that it is more difficult to insulate negative charges than positive ones

THE subject of electric figures and the differences between positive and negative electricity was prominently recalled by Prof. S. P. THOMPSON at the last meeting of the PHYSICAL SOCIETY in his Paper on "Electric Splashes." The figures shown, which were very beautiful, are produced by very simple means, and are strikingly illustrative of the differences between positive and negative charges.

AT the same meeting an exhaustive Paper on Galvanometers by Prof. AYRTON and his demonstrators, Messrs. T. MATHER and W. E. SUMPNER, was brought forward. The large number of instruments of all types at the Central Institution afford exceptional opportunities for comparison of their relative merits; and the information that has been collected there will, when published, be of great value to instrument makers and purchasers. The different points alluded to by Prof. AYRTON in describing the scope of the communication were very numerous, and the discussion of them was adjourned till February 7th, before which time we hope to publish a full abstract both of this paper and Prof. THOMPSON'S.

WE learn from the *American Journal of Science* that Messrs. TROWBRIDGE and SHELDON have been experimenting on the magnetic properties of alloys of nickel and tungsten, with the view of ascertaining whether the magnetic susceptibility of the nickel can be increased in the same way as that of steel is if alloyed with small quantities of tungsten. The results obtained show that the tungsten considerably increases the magnetic moment if the alloy is forged, while very little effect is produced if the alloy is cast. Moreover, variations in the proportions of tungsten and nickel do not seem to produce corresponding changes in the magnetic properties. Experiments of this kind are of great value, even if attended with but little success. We are quite ignorant of the reason why substances differ in magnetic permeability, in spite of the importance of the property to electrical engineers, and very possibly such investigations will lead to discoveries of the first importance to both science and practice.

AT the moment of going to press we learn that at their meeting held yesterday (Thursday) afternoon the Brighton Town Council adopted the electric light scheme, referred to in another column, by 35 votes to 3.

Cable Interruption.—The cable between Punta Rassa and Key West is at present interrupted.

Vera Cruz.—The municipality of Vera Cruz invite tenders for the electric lighting of the town.

Fareham.—Permission has been granted to the Fareham Electric Light Company to erect wires and posts in the town.

Carlisle.—At their last meeting the Town Council decided to oppose the Provisional Order of the Brush Electrical Engineering Company.

Royal Society.—Among the Papers down for reading yesterday was one by Dr. Hopkinson, on the "Physical Properties of Nickel Steel."

Cadiz.—The Corporation has signed a contract with Señor de la Viesca to light the streets of the town with 1,000 16 candle-power lamps.

North Berwick.—At the last meeting of the Town Council it was decided to support the Provisional Order of Messrs. Latimer Clark, Muirhead, and Co.

Electric Companies for 1889.—The *Investors' Guardian* for the 15th inst. gives the capital of the electrical companies formed in 1889 as £5,388,600.

Church Lighting.—The Chapel Royal, Savoy, is closed for the purpose of making the necessary arrangements for the installation of the electric light.

The Halifax-Bermuda Cable.—The Canadian Government has been informed that the cable from Bermuda to Halifax will be completed by the middle of June next.

Rochester.—The Rochester Town Council have decided not to oppose the Provisional Order of the Chatham, Rochester, and District Electric Lighting Company.

The Central London Railway.—At the last meeting of the Holborn Board of Works, it was decided not to offer any opposition to the Central London Railway scheme.

Glasgow.—The professional assistance of Mr. R. E. Crompton has been specially secured on behalf of the Corporation of Glasgow in reference to electric lighting matters.

Eastbourne.—At a special meeting of the Town Council on Wednesday, it was resolved by 16 votes to 3 to consent to the proposed Provisional Order of the Eastbourne Electric Light Company.

Interruption of Telegraphic Communication with Skye.—Telegraphic communication between the mainland and the Island of Syke has been interrupted by the breaking of the cable at Kyleakin.

Institution of Civil Engineers.—Amongst the recently elected Associate Members of the Institution of Civil Engineers, we note the names of Messrs. Albion T. Snell and A. A. Campbell Swinton.

Resignation of M. Coulon.—M. de Selves, Prefect of the Gironde, has been appointed Director of Posts and Telegraphs in the place of M. Coulon, who has been nominated to a post in the Council of State.

Gravesend.—The Parliamentary Special Committee of the Gravesend Town Council recommend the Council to take the necessary steps, at the first opportunity, to obtain a Provisional Order to supply electricity.

Oxford.—The Town Council last week, after a lengthy debate, decided to expunge from the Bill before Parliament the clauses relating to the purchase of the gas undertaking and those relating to the electric lighting.

The Electric Lighting of the Taj Mahal.—Prince Albert Victor visited, on Tuesday evening, the celebrated Taj Mahal, or mausoleum of Shahjehen and his consort at Agra, which was lighted by electricity for the occasion.

Chelmsford.—In consequence of the report of the Borough Surveyor on the danger to be apprehended from the electric light wires and posts, Major Cardew paid a visit to Chelmsford last week for the purpose of inspecting them.

Dundee.—The replies received to the circular sent out to the large gas consumers by the Electric Lighting Committee

Digitized by Google

inquiring whether these consumers would be prepared to adopt electric light, have proved very discouraging.

The Phonopore.—We hear that the Midland Railway Company instead of duplexing its London-Leicester wires in the ordinary manner as was originally intended, have decided to employ Mr. Langdon-Davies' phonopore apparatus.

Woking.—At the last meeting of the local sanitary authority it was decided to support the Provisional Order of the Electric Supply Company, but a motion that it was undesirable to erect overhead wires was subsequently unanimously agreed to.

The Van Rysselberghe System in Austria.—The authorities have decided to abandon the Van Rysselberghe system of simultaneous telegraphy and telephony on the Vienna-Brünn line, and to commence a telephone trunk line between these two towns early in the spring.

Plymouth.—The Town Council have decided to consent to the Provisional Order for which the Devon and Cornwall Electric Supply Company are applying, and to lodge objections with the Board of Trade to the Draft Provisional Order deposited by the Electric Trust Company.

Liverpool Physical Society.—At a meeting of this Society on the 20th, a Paper on Sir William Thomson's electric measuring instruments was read by Mr. C. H. Yeaman. The Paper was illustrated by diagrams, and various examples of the instruments described were exhibited on the table.

High Voltage Khotinsky Lamps.—The Société Khotinsky is now manufacturing 200-volt lamps of from 10 to 200 candle-power, and consuming 3·5 watts per candle. The filament is extremely fine, and to prevent breakage from oscillation the curls are kept in position by hooks attached to the top of the bulb.

London Tramways Company.—This company have introduced a Bill, which was considered by Mr. Campion, Examiner of Private Bills, yesterday, for the purpose of applying electricity as a motive power for their various systems of tramways, by means of wire ropes, chains, or electrical apparatus placed underground.

The Series Electric Traction Syndicate.—The Series Electric Traction Syndicate have concluded a contract to work the North-Western and Midland District Auxiliary Railway Company's line, 7¼ miles in length, by electricity. They have also contracted for the equipment of a further 15 miles of tramroads at present under construction.

National Telephone Electrical Society.—At a meeting of this Society last week, Mr. Fred Brown, of the Walsall Electrical Company, read a Paper on electric lighting. The lecture was rendered more interesting by a series of beautiful experiments. Samples of the various materials used in the practical work of electric lighting were also exhibited.

Hanover.—The lines of the Hanover Tramway Company are about to be extended by 40 kilometres. The extension will be worked by accumulator cars. The cells employed will be those of Messrs. Louis Blum and Co., of Marly, Switzerland, whose accumulators have been already employed at Hamburg. The cars also will be similar to those now running at Hamburg.

Surrey County Council.—At the last meeting of this Council the Highway Committee reported that they had instructed the clerk to dissent from the Brush Electrical Engineering Company's proposed Order for lighting Richmond. The Committee further reported that in their opinion a clause should be inserted in all electric lighting schemes providing that no overhead wires should be erected, and that underground wires should be laid. The report was agreed to.

Lectures on the Theory of Electrolysis.—A course of ten lectures by Mr. Holland Crompton on the theory of electrolysis and the nature of chemical change in solution commences today, at 4.30 p.m., at the Central Institution, Exhibition-road. In this course an account will be given of the recent development of the Clausius dissociation hypothesis of electrolysis by Arrhenius, Ostwal, and others; of Van't Hoff's extension of Avogadro's theorem to dilute solutions, and of Raoult's methods of determining the molecular weights of dissolved substances.

Westminster Vestry.—At the last meeting of this Vestry it was decided to grant consent to the applications of the Kensington and Knightsbridge Electric Lighting Company, the City of Westminster Electrical Syndicate, and Messrs. Renshaw, King, and Co. This action is taken in view of the fact that the Board of Trade granted Provisional Orders to the London Electric Supply Corporation and the Westminster Electric Supply Company, in opposition to the views of the Vestry.

Eastern Telegraph Company.—After protracted negotiations, the Eastern Telegraph Company has made a satisfactory agreement with the British and French Governments for a renewal of the lease of their special wire from London to Marseilles. The company will make a small annual saving in the cost of the wire. The company has secured the right for twenty years to land cables on the coast of France. Press rates will be introduced between France and her Eastern possessions of Cochin China, Annam, and Tonquin.

Proposed Association of Metropolitan Electric Lighting Companies.—A meeting was held last week under the presidency of Sir John Pender, at the offices of the Metropolitan Electric Supply Company, for the purpose of considering the desirability of establishing an Association of the Statutory Electric Lighting Companies within the Metropolis in order to promote the consideration of, and combined action upon, matters of general interest relating to electric lighting. Representatives of several of the leading companies were present, including Lord Crawford, Mr. Eustace Balfour, Mr. James Strick, and Mr. Browne-Martin.

Reduction in Telephone Charges.—The National Telephone Company announce to the subscribers to their Liverpool and district system that the rent for the use of telephones in that centre has been reduced from £20 to £15 per annum, and that arrangements are being rapidly completed for the establishment of telephonic communication between Liverpool and London. The same company also notify that on and after April 30th next the rate of the exchange subscription in Manchester will be reduced from £20 to £15. Subscribers whose contracts go beyond April 30th will be allowed a free extension of service equal to the difference between their contract rate and the reduced rate.

The London "Subway Railway" Bills.—The promoters of the London Central (Subway) Railway Bill have given an intimation of their intention not to proceed any further in the coming Session with their Bill which has been deposited. The promoters of the Kensington and Paddington (Subway) Railway Bill have also given notice that this Bill will not be further proceeded with. The abandonment of these two Bills—together with the North and South of London Subway Railway, and the City and North of London Subway Railway Schemes, the withdrawal of both of which has already been announced, leaves, of the five subway railway schemes originally projected by new companies, only the Central London Railway Bill to be proceeded with.

Brighton.—An important report by the Electric Lighting Committee was considered by the Town Council yesterday. Acting on the advice of Mr. Schoolbred, the Committee recommend—(1) That electric lighting works be established for the supply of electricity by the Corporation under the powers of "The Brighton Electric Lighting Order, 1883." (2) That the system of supply be the continuous current system at low pressure, combined with storage batteries. (3) That the area of supply defined in Schedule A to the Brighton Electric Lighting Order, 1883, be extended. (4) That works for the supply of electricity be forthwith established at an estimated cost of £30,000. (5) That the price to be charged for current be 6d. per unit.

Telephonic Extensions.—On Tuesday the trunk wire connecting Kidderminster with the general telephonic system of the National Telephone Company was formally opened by the Mayor of Kidderminster, who exchanged congratulations with the Mayors of Birmingham, Coventry, Derby, Burton, Wolverhampton, Walsall, Wednesbury, Bradford, and Nottingham. A congratulatory message was also sent to the Mayor of Man-

Digitized by Google

chester, and a conversation took place with the directors of the company at Edgware. It is anticipated that the wire will be carried into the city within the next month. The line has so far given very satisfactory results, direct communication *via* Birmingham having been established with Manchester, Bradford, and Leeds.

Mombassa Cable.—On the 19th inst. the Eastern and South African Telegraph Company completed the laying of a submarine cable 155 miles in length between Zanzibar and the headquarters of the Imperial British East African Company at Mombassa. So rapidly is the development of Africa proceeding that in a few years we shall probably hear of a railway and landline being constructed from Mombassa to the Lakes, which would immensely facilitate the work of explorers and the opening up of the interior to civilisation and trade. We understand that the Imperial British East African Company are about to construct landlines from Mombassa to all the small ports and native townships along the coast. When this is effected, as we have reason to believe it shortly will be, we may fairly anticipate a large augmentation of British trade, and facilities for explorers prospecting the country in such a manner as cannot fail to have a marked effect upon the future of the dark Continent.

Bradford.—An inquiry was held on Friday last before Mr. T. Codrington, M.I.C.E., inspector under the Local Government Board, and Colonel C. H. Luard, R.E., into an application by the Corporation for powers to borrow a further sum of £30,000 for the purpose of electric lighting. About £2,000 beyond the £20,000 originally authorised has been actually expended, and the £30,000, with regard to which the inquiry was held, is intended to cover that sum as well as the expenses of future extensions of the electric works. The immediate expenditure at present contemplated is only £10,000. The Town Clerk represented the Corporation, and no opposition was raised to the application. The inspector was supplied with information relating to the expenditure of the £20,000. The next point of inquiry was as to the sums of money which the Corporation had already obtained power to borrow by way of charge on the general district rate. It appeared that the Corporation might under existing powers borrow upon the rate to the extent of £2,000,000, but had at present only borrowed somewhat over £500,000. At the conclusion of the inquiry the inspector and Colonel Luard visited the electrical works.

Leeds.—A joint meeting of the Parliamentary Committee, the Electric Lighting Committee, and a sub-Highways Committee was held on Tuesday, for the purpose of considering the Provisional Orders sought by the several companies desirous of obtaining powers to light the borough by electricity. Applications for Provisional Orders have been made by the National Electric Supply Company, the Yorkshire House-to-House Electricity Company, and the Electric Installation and Maintenance Company. Alderman Spark moved as an amendment, "That the Council, as the local authority, be recommended to refuse its consent to the granting of Provisional Orders to the National Electric Supply Company, the Yorkshire House-to-House Electricity Company, and the Electric Installation and Maintenance Company within the borough of Leeds; and that the Council be recommended at the end of the six months referred to in the resolution passed on October 2nd, to instruct the Electric Lighting Committee to report upon the question of electric lighting with full information upon all improvements which have been made in supplying the light up to that time." Upon being put to the vote Alderman Spark's amendment was carried by a large majority. The Mayor has called a special meeting of the Council for Tuesday next to consider the question.

The Edinburgh Exhibition.—The Exhibition buildings are, we hear, making rapid progress. There are two principal buildings—one to contain the electrical and engineering exhibits, having a central span of 80ft. and two lateral galleries of 20ft. and 15ft. on each side, and about 800ft. long; and the other to contain the general industrial section, covering a space of about 250,000 square feet. These buildings present very handsome elevations, and already form prominent features of the district. The open weather has also facilitated the laying out of the grounds. The arc lighting has, as we have already announced, been placed in the hands of the Brush Electrical Engineering Company, and Messrs. King Brown and Co. undertake the principal portion of the incandescent system. There will be two special railway stations—North British and Caledonian—within the Exhibition grounds. As will be seen by our advertisement columns, tenders have also been invited for the working of a small electric railway. The line is intended to be not only a mere demonstration of the capabilities of electric traction, but to provide the visitors to the Exhibition with a means of getting from point to point in the grounds. The general management is in the hands of Mr. Lee Bapty, so that it may be expected that nothing will be omitted to ensure the success of the Exhibition. We hear that the available accommodation has been applied for more than three times over.

Private Bills in Parliament.—The Examiners of Private Bills have commenced their sittings, and amongst other Bills which they have had under consideration this week in which they have found compliance with the Standing Orders of Parliament, are the following:—The Central London Railway Bill (for incorporating the Central London Railway Company and for empowering them to construct underground railways or subways from Bayswater to the City, to be worked by electricity. The capital of the company is £2,500,000, and provision is made for paying interest out of capital during construction at a rate not exceeding 4 per cent.); the City of London and Southwark Subway (Clapham Extension) Bill (to empower the City of London and Southwark Subway Company to extend their authorised subway to Clapham. Power to raise additional capital not exceeding £200,000 is asked); the Strand Electric Lighting Bill and the St. Martin's-in-the-Fields Electric Lighting Bill (promoted for the purpose of authorising Messrs. A. and S. Gatti to erect and maintain electric lines and works and to supply electrical energy within the parishes of St. Paul, Covent Garden, St. Clement Danes, and St. Martin-in-the-Fields); and the City of London Electric Lighting Bill (for authorising the House-to-House Electric Light Supply Company to erect and maintain electric lines and works and to supply electrical energy within the City. The price for supplying the public lamps is, under the Bill, to be settled by agreement between the local authority and the undertakers).

The Civil and Mechanical Engineers' Society.—At the last meeting of this Society a Paper entitled "The Present Aspect of Electric Lighting in London" was read by Mr. E. C. de Segundo. The author held the fact that so many well-known commercial and professional men had connected themselves with companies as a proof that electric lighting was fairly on the way to assured success. He referred briefly to the various schemes on foot for the supply of electrical energy, but only considered two systems in any detail—that adopted by the London Electric Supply Corporation and that by the Metropolitan Electric Supply Company. He suggested, with regard to the former, that the use of engines of so large a horse-power might tell a great deal against the alleged economy of the whole system. There was also this further disadvantage: that should a bearing of the 10,000 horse engine or dynamo heat badly about 200,000 lights or their equivalent would be extinguished by the stoppage of the engine. He next spoke of the Metropolitan Electric Supply Company, and described how their supply of electrical energy was produced by a large number of small generating units distributed in groups over the area of supply. It was worthy of remark that the Metropolitan Company were building stations containing machinery of a type which involved no experimental element. He then referred briefly to the question of underground *versus* overhead mains, and after a few other remarks on matters of general interest connected with the subject, he concluded by stating that it was justifiable to assume that at present there was a "boom" in alternate-current machinery, and he would not be surprised to see supply companies adopt before long the high-tension continuous-current transformer system, inasmuch as it was probable that no great difficulty would be experienced in making the efficiency of the continuous-current transformer system compare very favourably with the mean efficiency of the alternate-current transformer system.

THE CLARK STANDARD CELL.

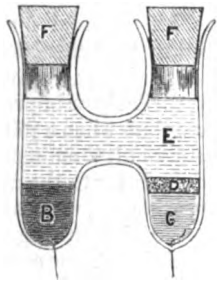
BY LORD RAYLEIGH, SEC. R.S.

In order to expedite the settlement of any open questions respecting Clark cells, I send the following remarks upon the Paper of Prof. Carhart, reprinted in *The Electrician*, p. 271, from the *Philosophical Magazine*, entitled "An Improved Standard Clark Cell with Low Temperature Coefficient."

In the first place Prof. Carhart appears to me rather to exaggerate the inconvenience arising from temperature changes in a Clark cell of ordinary construction. The coefficient is about ·00077 per degree cent., so that an uncertainty of a whole degree, affecting the E.M.F. by less than $\frac{1}{1000}$, would hardly be of practical importance. The sensitiveness to temperature is in fact only about the double of that of German silver resistance coils. In a suitable situation, and with the most ordinary care, the temperature would not be uncertain to more than one or two tenths. I have found it possible to work even closer than this in a room (next the roof), far from specially suitable, without any particular precautions; but if desired, it is easy to reduce the uncertainty under this head by some such plan as embedding the cell with a thermometer bulb in a vessel of sand.

The really serious question is whether the temperature or coefficient itself is liable to important variation without assignable cause. If it be uncertain whether the proper coefficient is ·00077, or, as in Prof. Carhart's cells, ·00039, the utility of the standard would indeed be seriously compromised.

Undoubtedly the lower coefficient would be an advantage in itself, if it could be obtained without loss in other respects. The principal feature insisted upon by Prof. Carhart is the separation of the zinc from the mercurous salt; but my experience is totally opposed to the view that the lower coefficient can thus be secured. The separation actually occurred in a large number of the cells upon which I experimented, especially in those of the H pattern,* where the mercury and mercurous salt occupied one leg, and an amalgam of zinc the other. The arrangement is shown in the figure.



H-Pattern Cell.

B, Amalgam of Zinc; C, Pure Mercury; D, Mercurous Sulphate; E, Saturated Solution of Zinc Sulphate; F, Corks. At the bottom of each leg of the cell a platinum wire sealed through the glass is shown.

That these cells have practically the same temperature coefficient as others in which the paste touches the zinc, is proved by Table XIII. of my second Paper.† I am thus at a loss to explain the low temperature-coefficient of Prof. Carhart's cells, unless indeed upon the supposition that his solutions were not throughout *saturated with zinc sulphate*. In this case the coefficient is just what might have been expected, for I found from two cells of this description the coefficient ·00038. It may be remarked that the H form is safer in this respect than those in which the zinc is at the top of the liquid, especially when removed from the paste; for the part of the liquid where saturation is of importance is that in contact with the zinc. At the top of the column the salt may easily become deficient, when the temperature rises, even though there be plenty of undissolved crystals below. The objections to unsaturated solutions are discussed in my Papers. They turn upon the difficulty of preparing a standard solution, and upon the liability to change with evaporation.

* *Phil. Trans.*, 1884.
† *Phil. Trans.*, 1885, § 40.

I quite agree with Prof. Carhart as to the importance of pure mercury. And there is undoubtedly something yet to be done in respect of the mercurous sulphate. I may remark that the sample used by me did not turn yellow when treated simply with zinc sulphate solution, but only when rubbed up also with *zinc carbonate*. In the cells made by Mr. M. Evans the paste was quite white, but this did not prevent the variation with temperature being the same as in other cases. (Table XIV., T_1, T_3).

I once came across a sample of mercurous sulphate with which it was difficult to prepare satisfactory cells. When rubbed up with zinc carbonate and zinc sulphate solution it turned dark green instead of yellow. Until the question is further elucidated I should be disposed to avoid a sample which behaved in this way.

UNDERGROUND MAINS.

BY G. L. ADDENBROOKE.

II

(*Continued from page 262.*)

Some doubt has been expressed as to the lasting qualities of lead laid in iron pipes; on this point, however, there is considerable evidence. In the Paper referred to in the first article, Mr. Fleetwood mentions that "in 1846 the Electric Telegraph Company decided to lay wires underground from their offices in the Strand to Nine Elms Station. Two lead tubes about ½in. in diameter covered with tarred yarn, each tube containing four copper wires wrapped with two layers of thick cotton, and the tube filled with a mixture of tar, resin, and grease, were drawn into a 3in. cast-iron socket pipe. The lead tubes were originally 50 yards in length. After the wires had been jointed, a pipe was drawn over the joints and soldered at each end. During the year 1887 some of this cable was recovered, when the wires were tested, and the insulation still appeared good. The tar appeared as fresh as when first put in the tube."

I have lately had an opportunity of seeing this cable, and the lead is as good as the day it was put into the iron pipe. In this instance the lead covering was protected by a wrapping of yarn, so that the lead was not in actual contact with the iron pipe, though if the yarn were damp a voltaic circuit would still be formed. To get a case where the lead is more directly in contact with the iron, we cannot do better than instance the pneumatic despatch system of the General Post Office. In this system the despatch tubes are of lead laid in iron pipes, the only thing between being the coating of Angus composition with which the iron pipes are coated, but which must be rubbed off in many places when the lead tube is drawn into the iron one. In this case no detrimental action has been traced, and the pipes appear to last perfectly when not subjected to mechanical accidents.

It may be objected here that there is no electrical current passing in the pneumatic tubes, and that, therefore, this case cannot be treated altogether as a valid argument, that no action does occur when an electric current is flowing through the lead tube, which current may leak slightly through the insulation. It, however, appears to me that the lead being in contact with the iron in many places, a metallic path for this current—when it exists—is easily open from one conductor to the other or to earth, without passing through any electrolyte, whereas from this very position, viz., the lead being in metallic contact with the iron, should damp be present, local circuits of comparatively low resistance would be set up, and in these circuits currents would flow large in quantity, though of low electromotive force, and likely to cause more action than anything due to a slight leakage of current in the mains.

There is another class of materials largely used as a protective covering for cables, viz., jute, yarn, and cotton for braids and tapes. As these are more or less perishable it is a matter of great importance to be able to form an idea of how long they are likely to last under given circumstances. When exposed to the weather in London, my experience is that however well compounded such tapes and braids may be, the outer cover-

Digitized by Google

ing will be reduced in strength in a couple of years, or perhaps less, and that in two more years there will be very little power of holding together in the material; this is the result of alternate wettings, dryings, and the action of the sun and air. Fortunately, however, materials laid under water or in iron pipes have a much longer life. I have already referred to the fact that the lead-covered cable mentioned in the extract quoted above was covered with tarred yarn. Now, this tarred yarn seems to be in almost as good condition as if it were new, and still to preserve nearly its full strength, although it was in the iron pipe buried in the ground forty-one years. It is worth mentioning also that the compounded tape covering used by the Post Office authorities to protect their gutta-percha wires underground appears to last well, having probably quite a 10 years' life on an average, though naturally a good deal depends on local circumstances. The Post Office engineers always have their gutta-percha covered wire for underground work taped and not braided. Braiding is a stronger covering, and better adapted for overhead work than tape, but for underground work it is much easier to uncoil the tape and inspect the insulation or take out faults than it would be if the wire were covered with braid, every inch of which must be cut off with a knife at some risk of damaging the insulation, while, again, the braiding cannot be replaced. I mention this as a matter of practice, though it is doubtful if the same reasoning applies with equal force to the larger cables used for electric lighting. There is another point of Post Office practice which those who are likely to have to pull several cables into the same pipe would do well to bear in mind. It is this: when the Post Office engineers want to put a new wire in a section, they do not simply draw in the extra wire, but they withdraw all the wires in the pipe, and then, adding the new wire to them, draw the whole lot back again. This may seem a cumberous, expensive, and roundabout proceeding, but it is necessary, for if the apparently easier method of drawing the extra wire in is used, the weight of the wire as it is being pulled along causes the wire to lie in a fixed course, consequently all the friction occurs in well defined places, and it is found that the new wire crossing older ones in several places, as it is certain to do, will be almost sure to chafe through the insulation of some of the older wires, or damage them so as to give rise later on to faults. As above mentioned, the Post Office use only a single tape to cover their conductors, and therefore the insulation will be more easily injured than that of electric light cables, which are usually protected by a heavy double-braid or lead-covering, so that this experience of the Post Office may rather be taken as a caution than as a prohibition. It is to obviate the risk of this chafing taking place that several systems of conduits have been devised, having a separate pipe or space for each cable, but by making the pipes or holes small, the friction when drawing cables in becomes much greater, particularly if the conduit is at all out of the straight; in this case the position of things is such as to somewhat resemble trying to pull a rope round a stationary grooved fly-wheel. The system of underground mains used by the Post Office for many years consists of 3in. socket cast-iron pipes, lead-jointed, and laid under the footpaths. The pipes open into shallow manholes at convenient distances, the manholes being made as watertight as possible, and being provided with a cover, to lie flush with the pavement, of paving stone or cement in an iron setting, which is less slippery than iron alone. These man-holes are situated on an average about seventy yards apart. Into the pipes such number of single wires as are required are drawn in together, the wires being all straight and separate and not made up in the form of a cable. When wires of a greater length are required to be drawn in than can be done at once, they are drawn through a certain distance and then coiled up; the coil is next turned over and the cable drawn through a further section, and coiled up again.

I have made a good number of inquiries to find out what is the state of the atmosphere inside these and other similar pipes used for electric lighting. However well made the joints of the pipes may be, we may take it that with a few exceptions the interior will always be damp, this damp no doubt largely arising from warm and moist air from outside entering the pipes, which as a rule will be cooler than the atmosphere. The presence of damp makes the soundness of the insulation a matter of the first importance; but as all the materials which are likely to be used in the construction of the mains stand damp well, though they may not stand alternations of damp and dryness, this, if an objection at all, is a smaller one than it might at first sight seem.

There is another system of underground mains of great originality which has been used in America with considerable success for telegraphic and telephonic purposes, and in one or two instances in this country. I allude to the Brooks system. Here the conductors are wrapped with cotton or yarn, the material not being intended so much to insulate them from each other as to keep them apart, the insulation being effected by a heavy liquid petroleum. To carry out this system, and taking as a sample the trial section which was laid some years ago between Waterloo and Nine Elms, and is still being used for part of the distance, a line of screw-jointed iron piping is laid, the wires, wrapped as above, being then drawn into it. The pipe is laid as far as possible on a slight upward or downward slope, and small screw-plugs are inserted at every highest point. At one end of the piping a reservoir is provided at some height above the highest point in the piping, and this reservoir is filled with petroleum. The petroleum is run into the pipe to fill it as far as possible, and then the screw-plugs are taken out one by one, and all included air blown off, so that the pipe becomes entirely filled with petroleum from end to end. The supply tank being kept with a quantity of petroleum in it, makes up for any leakage that may occur, which is usually slight, and the insulation of the wires is found to be high and very uniform. The actual insulation depends a good deal on the class of petroleum used, and the extent to which previous moisture has been got out of the pipe by flowing petroleum through it, and leaving it to settle afterwards. If the pipes have been well laid the loss of petroleum by leakage is very trifling, and the system has every appearance of lasting qualities, since as long as the iron pipe is not eaten through from the outside there is nothing to deteriorate. With a little modification feeders could be laid for electric lighting in this manner, which would doubtless work satisfactorily, as they would not require to be got at, at intervals, when once put down, but for mains supplying customers and requiring to be tapped at frequent and uncertain intervals the liquid insulation presents difficulties not easy to overcome.

When india-rubber cables are used for high-tension currents a good deal has been said as to difficulties in maintaining the insulation satisfactorily at the joints, although the main cable may be perfectly sound. Now, carlessly or improperly-made joints may easily give rise to trouble, but when a joint is well and properly made—and it is not at all difficult to make such a joint—its powers of resistance are but little inferior to the main cable. In this connection the following experiments, tried at Messrs. W. T. Henley and Co.'s a few weeks ago, are interesting. Messrs. Henley had a piece of 19/18 cable insulated with one coat pure rubber, one coat drab rubber, and one coat black rubber vulcanised, and one coat of proof tape, the total thickness of the insulation amounting to 60 millimetres, or rather less than $\frac{1}{16}$in. About the centre of this length of cable a piece of the insulation was cut out, leaving the bare copper. The ends of the insulation were pared down so as to leave a tapering surface, and a very small amount of rubber solution was rubbed over their surfaces, and then about five lappings of pure rubber strip were tightly wound on with the merest trace of the solution. These lappings brought up the insulation to about what it was in the rest of the cable. After the joint was made it was put in water and subjected to a pressure of 1,000 Leclanché cells, or about 1,450 volts, through a sensitive reflecting galvanometer, when no leakage whatever could be detected. At the date of the further tests, two months afterwards, this piece of cable had been alternately in and out of water all the time. Tested again in water with 1,450 volts, it appeared quite perfect. Taken out of the water it was bent so that the portion where the joint was, made a rectangular curve in this form ⌐; it was then straightened, and the process repeated four times. Tested again, no effect was observable. The cable was then taken and the jointed portion wrapped round a rod 1¼in. in diameter, four coils in all being made. This would compress the insulation in the inner side and extend that on the outer side. In this position the cable was again tested in water, but still no difference was observed on the galvanometer. Lastly,

Digitized by Google

the coil was unwrapped and the cable straightened out, and, being put in water, the 1,450 volts were again applied Even after all this ill-usage the cable and the jointed portion still showed no signs of weakness. A joint as good as this can easily and certainly be made anywhere on a system of mains, and if well protected by a stout covering of compounded tape should remain in perfect condition for an indefinite number of years. I mention these experiments not as advocating specially the use of india-rubber covered cables, but as tending to show that should other cheaper materials prove unsatisfactory, we have always this form of insulation to fall back upon.

(To be continued.)

THE ST. JAMES' AND PALL MALL ELECTRIC LIGHT COMPANY'S CENTRAL STATION.

The central station of the above company is situated in the centre of Mason's-yard, Duke-street. The boiler-room and generating-room have been dug out underneath the yard, and a three-story fire-proof building of white brick, used for stores and offices, is carried upon iron pillars and girders in the centre. The station is laid out upon the three-wire system for a total capacity of 20,000 16 candle-power lamps, which are run direct from the dynamos. A battery of accumulators, consisting of 240 cells, of Elwell-Parker's 31 L type, connected in two sets of 120, are provided on the ground floor, and will be employed to act as regulators and to supply night lights during the small hours. After going round the station, one cannot help feeling that the whole of the arrangements and apparatus in course of construction are of an intensely practical character. Every adjustment and manipulative act can be effected with ease and certainty by the attendant, while automatic gear has been fitted wherever suitable. Moreover, the designs have been executed with a view to adding further automatic gear as experience shall show to be advantageous and practicable. This system of going to work has the great advantage that the station has a good chance of keeping a clean record from the start—which the Pall Mall Company has done so far—and is, from the customer's and the shareholder's point of view, far preferable to the opposite plan of loading up the station from the outset with complicated and more or less untried automatic apparatus.

The boiler-room occupies the space nearest Duke-street. In one corner of it an artesian well is being bored, which is to reach to a depth of 380ft. The water from this will be stored in an underground reservoir of 12,000 gallons capacity, while the connection with the town supply will be retained in case of need. The boilers are of the loco type, constructed by Messrs. Davey, Paxman, and Co. They measure 20ft. 5in. in length by 6ft. diameter of barrel. The total heating surface is 1,720 square feet, with a grate area of 33½ square feet. They are constructed of mild steel for a working pressure of 170lb. per square inch. When the plant is complete there will be six of these boilers, having a total horse power of 2,400. Three Worthington pumps force the feed-water through two Berryman feed-water heaters, 22ft. high and 6ft. in diameter, in which by means of the exhaust steam the water is heated to 212° F. Injectors taking water direct from reservoir are fitted to each boiler in case of accident to the pumping system.

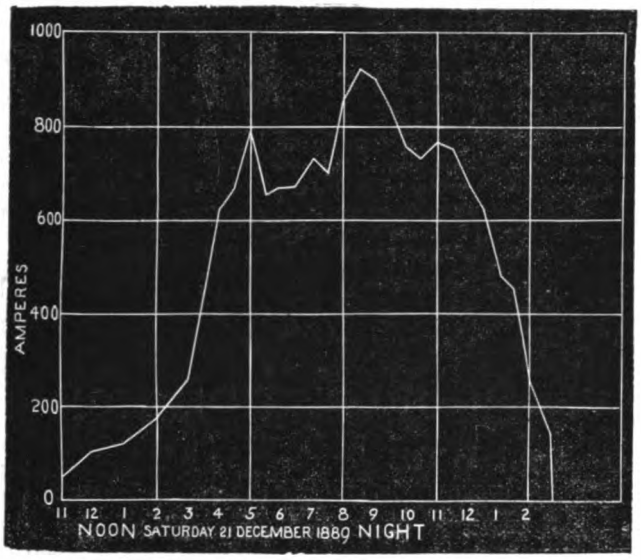
The generating-room will contain 10 Willan's central-valve engines capable of developing 210 horse-power at 350 revolutions, and two similar ones capable of developing 80 horse-power each. The engines are mounted on combination bed-plates, upon the other halves of which the field magnets and bearings of the dynamos are supported, the armatures being coupled direct to the engine shafts. The field-magnets of the dynamos are vertical, with poles downwards and supported by brass brackets from the bed-plates. The armatures are of the drum type, with the winding built up of strip and bar copper. The capacity of the 10 larger dynamos is 1,700 16 candle-power lamps each, and of the two smaller ones 700 16 candle-power lamps. They are all capable of working up to 125 volts, so that accumulators can be charged when desired. Regulation is effected by inserting resistance into the magnet circuits, which are shunts on the main. Each dynamo is provided with a switch in the shunt circuit, which is arranged so that on opening the circuit a resistance is connected across its ends through which the extra current flows, and risk of breaking through the insulation of the coils is thereby avoided. The generating sets are ranged in two rows of six each, one on either side of a central gangway, towards which all the commutators of the dynamos are directed. The main distributing and switch board will be placed at the end of the gangway distant from the boiler-house. Provision has been made against breakdown or stoppage from accident to the steam pipes by carrying them completely round the boiler-house and generating-room, and arranging stop valves and connections so that any repairs can be effected without throwing more than one boiler or two engines out of use.

The connections from the dynamos to the switch board consist of heavy insulated cables carried in porcelain insulators on brackets screwed to the overhead girders. The connection is for parallel work on a three-wire system of mains. The left-hand terminals of all the machines are connected together; the connecting cables pass first through automatic switches, which are mounted on the tops of the dynamos, and which are designed to automatically disconnect the dynamo on shutting down when the current has fallen to about 50 amperes, after leaving which they pass overhead to the switchboard, where each is connected by means of a fuse to the collecting bar. From this bar connection is made through an ammeter to the intermediate main. The other terminals of the dynamos are connected each to a gun-metal stud situated midway between two horizontal bars, to which the two outer of each of the three mains forming the feeders are connected. A gun-metal strap or bridge-piece is hinged by one end to the stud, and the other end can be clamped to either one or the other of the two bars. Thus, by shifting the strap round from one bar on to the other, any dynamo can be put on to either side of the three-wire system. As, however, this change necessitates the reversal of the polarity of the dynamo, one end of the shunt coil of the dynamo is also connected to this same stud and strap, the effect of which is that the polarity of the machine is reversed by the same operation by which it is changed over on the mains. The regulating apparatus for the shunt circuits of the dynamos is mounted at the foot of the main switchboard. A commutator switch of twelve sections, between each of which a resistance coil is connected, is mounted so that a rocking handle which carries the movable contact comes directly under the line of connections belonging to the dynamo which the switch regulates. On either side of a fixed spindle, upon which all the rocking handles are pivoted in line, runs a shaft, parallel with the fixed spindle. Each shaft is fitted with a pinion sliding on a feather, so that it can be slipped into or out of gear with spur wheels which are connected to the rocking handles. When a dynamo is coupled into circuit, both the pinions are thrown out of gear, and the rocking handle adjusted until the dynamo is doing its proper share of the work. When this is the case, one or other of the pinions is thrown into gear with the spur wheel, depending, of course, upon which side of the system the dynamo is connected to. Being thus adjusted relatively to the other dynamos, the rocking handle is moved—in common with the others which are already in gear—by a 15in. handwheel, with which both shafts are fitted. The other ends of the shafts are left to be fitted with automatic gearing.

The system of underground mains adopted by the St. James' and Pall Mall Company has on one or two occasions been severely criticised, but the company's engineer, Mr. Dobson, to whose courtesy we are indebted for these particulars, is confident that the precautions taken to avoid flooding or the accumulation of water or gas in the culverts are sufficient to guard against all difficulty from that cause. In support of his view that the system of bare conductors in iron culverts is good and practical, he has the fact that they have been in use in connection with the Pall Mall Station since April 4, 1889. Also in Berlin, where there has been plenty of experience with armoured cables, the air-insulated culvert system is being adopted.

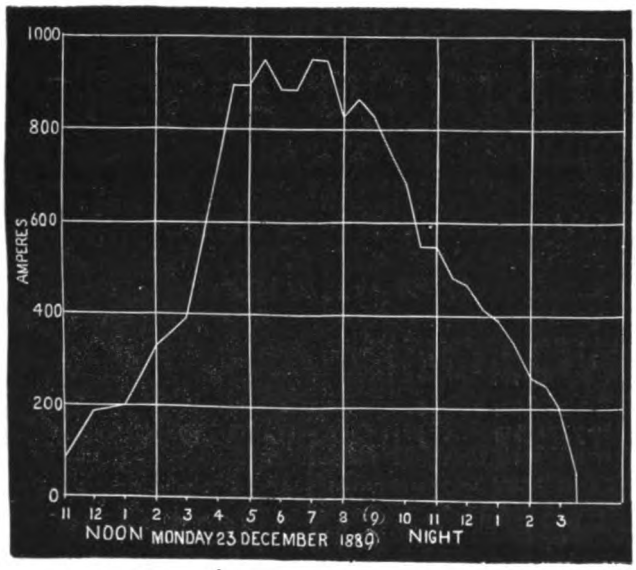
Digitized by Google

The largest main consists of eight strips of copper, 2in. wide by 0·1in. thick, or 1·6 square inch section; the two outside mains are of this size, while the middle one has a section of 0·8 square inch. The strips are supported on porcelain insulators, and spaced by means of porcelain jockeys, the whole being carried in a cast-iron culvert, the joints of which are leaded and the covers bolted on with a yarn and red-lead joint. Junction boxes are formed at frequent intervals; they are built of brick, with cast-iron frame covers and stone centres.



St. James' Station—Load Diagram No. 1.

The culverts, wherever possible, are laid with a fall towards the junction boxes, and each junction box is drained into a gully running into the main sewer. Wherever a dip occurs which cannot be drained direct a syphon-box and hydrant is fitted, so that any water which may collect can be pumped out in the same way as is done with gas mains. The mains are coupled up with fuses in the junction boxes, so that by simply bridging a fuse with a flexible cable and clips while it is removed, and then snapping off the clips, a line main can be

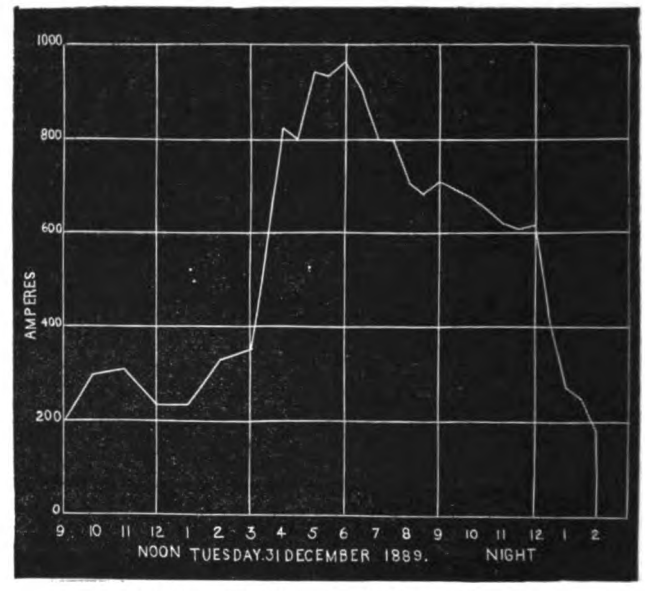


St. James' Station—Load Diagram No. 2.

disconnected for testing purposes. The service wires are of best vulcanised cable, led through gas piping which is brought through the bottom of the culvert, and secured with two back nuts. All connections to the strip mains are soldered.

The distributing system consists of a complete ring main running round Piccadilly, Regent-street, Waterloo-place, Pall Mall, and St. James'-street. This is fed by six heavy feeders, and radial distributing mains run out beyond the ring. From each feeding point on the ring pilot wires are run back to the station, so that the pressure at each point can be ascertained. The pressure on the ring main is kept constant at 107 volts, and houses connected to this main are supplied with 106 volt lamps. The voltage of the houses nearest to the station is 108, while those farthest from the station are reduced to 104. Thus the maximum variation is two volts, while the most important installations, which are on the ring main, are kept constant.

The company supply contractors for wiring houses to be connected with their mains, with a printed set of rules, which must be complied with, or connection with the main is refused. We omitted to mention one important use which it is intended to make of the accumulators, which is to fill up the gaps between the larger machines, so that they always work at an economical load. Among the more important installations supplied by the company are Her Majesty's Theatre, where a battery, placed in the theatre, is employed for the stage lighting, connected as a regulator across the mains—the Salisbury, Marlborough, Thatched House, Windham, Junior United Service, Arthur's, Oxford and Cambridge, Orleans, Brooks', Racing, and Corinthian Clubs; St. James' Hall, Moore and Burgess, the Egyptian Hall, Hotel Continental, Christie and Manson's, &c. The daily load curves taken at the station, some of which



St. James' Station—Load Diagram No. 3.

we reproduce, are quite of an exceptional character, the heavy demand being much longer sustained than in any others we have seen.

THE ROSEBRUGH DUPLEX TELEPHONE SYSTEM.

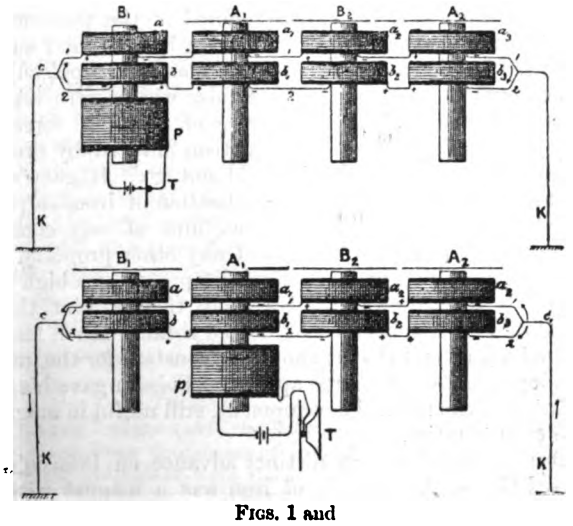
We are indebted to our esteemed contemporary the *Electrical World* of New York for the following description of a system of duplex telephony, which has recently been brought out in America by Dr. Abner M. Rosebrugh and his son, Mr. P. R. Rosebrugh, of Toronto.

In Figs. 1, 2 and 3, B_1 and A_1 are duplex or differentially-wound telephonic transmitters; B_2 and A_2 are correspondingly wound receivers. In Fig. 1, B_1 is transmitting and B_2 is receiving, and in Fig. 2 A_1 is transmitting and A_2 receiving. No. 1 and No. 2 are the two wires of the metallic circuit, and K and K are ground wires. The transmitters B_1 and A_1 are provided with a primary wire and with two secondary coils on a soft iron core, while the receivers B_2 and A_2 have two coils on a soft iron core magnetised by a permanent magnet. The coils a, a_1, a_2 and a_3, are in circuit with No. 1 wire, while the coils b, b_1, b_2, and b_3 are in circuit with No. 2 wire. The coils p and p_1 are primary coils, and are in circuit with a local battery

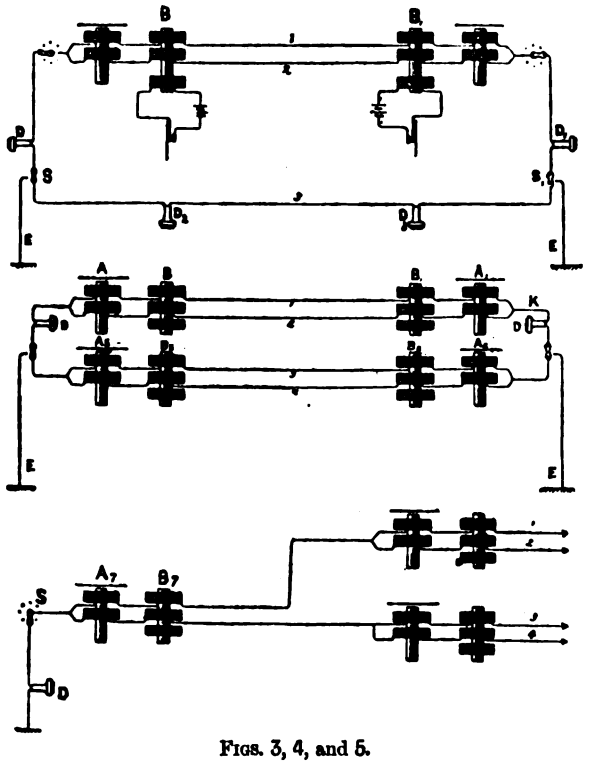
Digitized by Google

and a microphone, T. Following No. 1 wire from the point c in the direction of the arrows from left to right, it will be seen that the wire enters the coil a by the outside terminal, marked +, and makes its exit by the inside terminal, marked −. The connection is the same with a_1, a_2 and a_3, and on tracing the connection of the wire No. 2 from the point c_1 to c it will be seen that the coils b_2 and b are connected from the outside to the inside, while the coils b_3 and b_1, on the contrary, are connected from the inside to the outside.

Referring to Fig. 1, it will be seen that upon operating the microphone T the soft iron core will generate secondary currents in the coils a and b, presumably of equal strength, and as



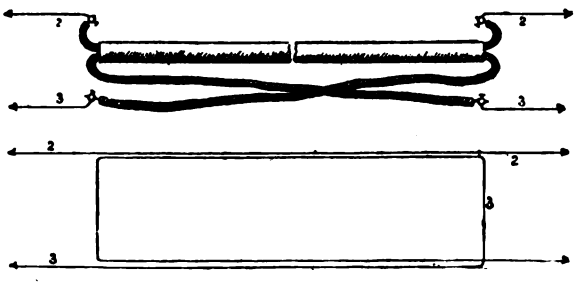
FIGS. 1 and



FIGS. 3, 4, and 5.

the outside or + wire of coil a is connected with the inside or − wire of coil b and on corresponding ends, the current from a will reinforce the current from b, and a current will be generated in the metallic circuit in the direction indicated by the arrows, the current in No. 1 wire moving in one direction and the current in No. 2 wire moving in the opposite direction. It will also be seen that from the peculiarity of the connection of the coils at A_1 and A_2 the currents in coil a_1 will neutralise the currents in b_1, and the currents in coil a_3 will neutralise the currents in b_3, whereas, on the contrary, the currents in coils a_2 and b_2 will reinforce each other; hence the receiver B_2 will respond to the transmitter B_1, while the receiver A_2 will be neutral thereto. Again, referring to Fig. 2, it will be seen that by operating the microphone T, independent secondary currents will be generated in coils a_1 and b_1, and will move toward the point c on wires 1 and 2, and in the same direction as indicated by the arrows. At the point c these currents meet, and were it not for the ground wire K they would neutralise each other; whereas, on the contrary, they reinforce each other on wire K, and proceed to "ground," and from ground to K, and to c_1, where they redivide and return to a_1 and b_1, by the wires 1 and 2. As the coils a_3 and b_3 are similarly connected and the currents traverse the two wires in the same direction, receiver A_2 will respond, and, as the coils a_1 and b_1 are similarly connected, A_1, were it a receiver, would also respond. On the contrary, as the coils of B_1 and B_2 are dissimilarly connected, these receivers will remain neutral; hence, when B_1 transmits to B_2, A_1 and A_2 are neutral, and when A_1 transmits to A_2, B_1 and B_2 are neutral. In the former case the currents traverse the two wires of the metallic circuit in opposite directions, and in the latter case the currents move on the two wires in the same direction, the circuit being completed by means of the ground or by a return wire. The same object may, of course, be attained in other similar ways.

In Fig. 3, 1 and 2 are the two wires of a metallic circuit. By means of the switches S and S_1, the two subscribers D and D_1 may either use a ground wire or a metallic circuit return wire at pleasure. In Fig. 4 the arrangement is the same as in Fig. 3, but the two wires, 3 and 4, are used as a common return wire. In Fig. 5 the branch line is also represented as being duplexed, A_7 B_7 representing duplex telephonic apparatus in the branch lines. In this latter arrangement it will be seen that with two metallic circuits three operators and a subscriber at each end of the line may communicate with each other simultaneously without interference. In this arrangement two or more wires are used as a single conductor. This increases the cross-section of the conductor and necessarily facilitates long-distance telephony.



FIGS. 6 and 7.

When telephone wires are conducted parallel to each other, particularly on long lines, they affect each other, as is well known, by induction. Various ways may be used to overcome these effects when one or both of the wires form part of a metallic circuit—as, for instance, a section of one wire may be brought within close proximity with the other, but the direction reversed. To accomplish this Messrs. Rosebrugh use a cable with two insulated wires, the terminals of which are connected, the one with wire No. 2 direct and the other with wire No. 3 reversed, as shown in Fig. 6, or the wires may be connected, as indicated in Fig. 7.

The Rubber Trade with Brazil.—A meeting of those interested in this trade was held at the London Chamber of Commerce on Tuesday to protest against the concession by the Provincial Government of Para, under which the Companhia Mercantil has power to compel all other export buyers of rubber to pay 20 reis for each kilogramme of rubber purchased by them from the receivers. A resolution approving the forwarding of a memorial to Lord Salisbury with a statement of the case was unanimously adopted According to later information this concession has been cancelled.

THE INSTITUTION OF ELECTRICAL ENGINEERS.

DR. JOHN HOPKINSON'S PRESIDENTIAL ADDRESS.

Magnetism.

(Continued from page 271.)

Prof. Tomlinson has investigated how many other properties of iron depend upon the temperature. But the most significant phenomenon is that indicated by the property of recalescence. Prof. Barrett, of Dublin, observed that if a wire of hard steel is heated to a very bright redness, and is then allowed to cool, the wire will cool down till it hardly emits any light at all, and that then it suddenly glows out quite bright again, and afterwards finally cools. This phenomenon is observed with great difficulty in the case of soft iron, and is not observed at all in the case of manganese steel. A fairly approximate numerical measurement may be made in this way: Take a block of iron or steel on which a groove is cut, and in this groove wind a coil of copper wire insulated with asbestos; cover the coil with many layers of asbestos; and finally cover the whole lump of iron or steel with asbestos again. We have now a body which will heat and cool comparatively slowly, and which will lose its heat at a rate very approximately proportional to the difference of temperature between it and the surrounding air. Heat the block to a bright redness, and take it out of the fire and observe the resistance of the copper coil as the temperature falls, due to the cooling of the block. Plot a curve in which the abscissæ are the times, and the ordinates the logarithms, of the increase of resistance of the copper coil above its resistance at the temperature of the room. If the specific heat of the iron were constant, this curve would be a straight line; if at any particular temperature latent heat were liberated, the curve would be horizontal so long as the heat was being liberated. If now a block be made of manganese steel, it is found that the curve is very nearly a straight line, showing that there is no liberation of latent heat at any temperature. If it is made of nickel steel with 25 per cent. of nickel, in its non-magnetic state, the result is the same—no sign of liberation of heat. If now the block be made of hard steel, the temperature diminishes at first; then the curve (Fig. 11) which represents the tempera-

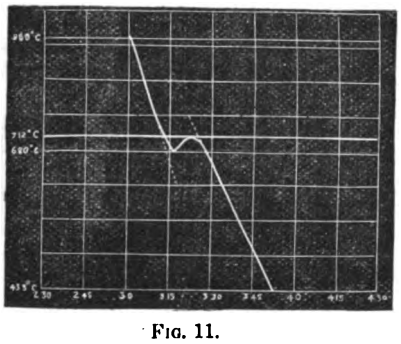

Fig. 11.

ture bends round: the temperature actually rises many degrees whilst the body is losing heat. The liberation of heat being completed, the curve finally descends as a straight line. From inspection of this curve it is apparent why hard steel exhibits a sudden accession of brightness as it yields up its heat. In the case of soft iron the temperature does not actually rise as the body loses heat, but the curve remains horizontal, or nearly horizontal, for a considerable time. This, again, shows why, although a considerable amount of heat is liberated at a temperature corresponding to the horizontal part of the curve, no marked recalescence can be obtained. From curves such as these it is easy to calculate the amount of heat which becomes latent. As the iron passes the critical point it is found to absorb about 200 times as much heat as is required to raise the temperature of the iron 1 degree centigrade. From this we get a very good idea of the importance of the phenomenon. When ice is melted and becomes water, the heat absorbed is 80 times the heat required to raise the temperature of the water 1 degree centigrade, and 160 times the heat required to raise the temperature of the ice by the same amount. The temperature of recalescence has been abundantly identified with the critical temperature of magnetism.* I am not aware that anything corresponding with recalescence has been observed in the case of nickel. Experiments have been tried, and gave a negative result, but the sample was impure; and the result may, I think, be distrusted as an indiaction of what it would be in the case of pure nickel. The most probable explanation in the case of iron, at all events, appears to be that when iron passes from the magnetic to the non-magnetic state it experiences a change of state of comparable importance with the change from the solid to the liquid state, and that a large quantity of heat is absorbed in the change. There is, then, no need to suppose chemical change; the great physical fact accompanying the absorption of heat is the disappearance of the capacity for magnetisation.

What explanations have been offered of the phenomena of magnetism? That the explanation must be molecular was early apparent. Poisson's hypothesis was that each molecule of a magnet contained two magnetic fluids, which were separated from each other under the influence of magnetic force. His theory explained the fact of magnetism induced by proximity to magnets, but beyond this it could not go. It gave no hint that there was a limit to the magnetisation of iron—a point of saturation; none of hysteresis; no hint of any connection between the magnetism of iron and any other property of the substance; no hint why magnetism disappears at a high temperature. It does, however, give more than a hint that the permeability of iron could not exceed a limit much less than its actual value, and that it should be constant for the material, and independent of the force applied. Poisson gave his theory a beautiful mathematical development, still usefnl in magnetism and in electrostatics.

Weber's theory is a very distinct advance on Poisson's. He supposed that each molecule of iron was a magnet with axes arranged at random in the body; that under the influence of magnetising force the axes of the little magnets were directed to parallelism in a greater degree as the force was greater. Weber's theory thoroughly explains the limiting value of magnetisation, since nothing more can be done than to direct all the molecular axes in the same direction. As modified by Maxwell, or with some similar modification, it gives an account of hysteresis, and of the general form of the ascending curve of magnetisation. It is also very convenient for stating some of the facts. For example, what we know regarding the effect of temperature may be expressed by saying that the magnetic moment of the molecule dimishes as the temperature rises, hence that the limiting moment of a magnet will also diminish; but that the facility with which the molecules follow the magnetising force is also increased, hence the great increase of μ for small forces, and its almost instantaneous extinction as the temperature rises. Again, in terms of Weber's theory we can state that rise of temperature enough to render iron non-magnetic will not clear it of residual magnetism. The axes of the molecules are brought to parallelism by the force which is impressed before and during the time that the magnetic property is disappearing; they remain parallel when the force ceases, though, being now non-magnetic, their effect is *nil*. When, the temperature falling, they become again magnetic, the effect of the direction of their axes is apparent. But Weber's theory does not touch the root of the matter by connecting the magnetic property with any other property of iron, nor does it give any hint as to why the moment of the molecule disappears so rapidly at a certain temperature.

* I have only recently become acquainted with the admirable work of M. Osmond on recalescence. He has examined a great variety of samples of steel, and determined the temperatures at which they give off an exceptional amount of heat. Some of his results are apparent on my own curves, though I had assumed them to be mere errors of observation. For example, referring to my Royal Society Paper, there is, in Fig. 38, a hint of a second small anomalous point a little below the larger one. And comparing Figs. 38 and 38A we see that the higher the heating the lower is the point of recalescence; both features are brought out by M. Osmond. The double recalescence observed by M. Osmond in steel with a moderate quantity of carbon I would explain provisionally by supposing this steel to be a mixture of two kinds which have different critical temperatures. Although M. Osmond's method is admirable for determining the temperature of recalescence, and whether it is a single point or multiple, it is not adapted to determine the quantity of heat liberated, as the small sample used is enclosed in a tube of considerable mass, which cools down at the same time as the sample experimented upon.

Ampère's theory may be said to be a development of Weber's: it purports to state in what the magnetism of the molecule consists. Associated with each molecule is a closed electric current in a circuit of no resistance; each such molecule, with its current, constitutes Weber's magnetic molecule, and all that it can do they can do. But the great merit of the theory—and a very great one it is—is that it brings magnetism in as a branch of electricity; it explains why a current makes a magnetisable body magnetic. It also gives, as extended by Weber, an explanation of diamagnetism. It, however, gives no hint of connecting the magnetic properties of iron with any other property. Another difficulty is this: When iron ceases to be magnetisable, we must assume that the molecular currents cease. These currents represent energy. We should therefore expect that, when iron ceased to be magnetic by rise of temperature, heat would be liberated; the reverse is the fact.

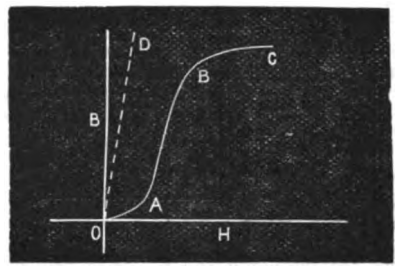
So far as I know, nothing that has ever been proposed even attempts to explain the fundamental anomally, Why do iron, nickel, and cobalt possess a property which we have found nowhere else in nature? It may be that at lower temperatures other metals would be magnetic, but of this we have at present no indication. It may be that, as has been found to be the case with the permanent gases, we only require a greater degree of cold to extend the rule to cover the exception. For the present, the magnetic properties of iron, nickel, and cobalt stand as exceptional as a breach of that continuity which we are in the habit of regarding as a well-proved law of nature.

DISCUSSION.

THURSDAY, JANUARY 9.

Sir WILLIAM THOMSON said the President had done well to emphasise the marvellous properties of iron, nickel, and cobalt, but he thought these properties were not quite so much isolated as would appear from the address. Faraday showed the continuity between paramagnetic and diamagnetic bodies, and that all substances are susceptible to magnetism when subjected to sufficiently intense magnetising forces. He had also compared the relative susceptibilities of materials, such as glass, bismuth, wood, &c.; but the absolute determination of their susceptibilities still presents a large field for interesting and valuable research. The fact that the magnetic properties of such substances could be compared was itself of immense importance, whilst Tyndall's observations on the properties of bread, Iceland spar, &c., which can be made, or are naturally anisotropic, further enhances the interest connected with the subject. The prodigious difference between the magnetic properties of iron, nickel, and cobalt, and those of other substances the speaker considered to be one of the great marvels of nature, and many ideas had been suggested by the President's address which so forcibly emphasised these great distinctions. Referring to the absence of deflection of the ballistic galvanometer when a copper core is withdrawn from a coil, he said this does not prove that no effect takes place in the copper during the process, for in reality two equal and opposite effects occur in rapid succession, thus neutralising each other's influence on the slow moving needle. In iron however, in addition to these induced currents in the metal itself, a change in the induced magnetism makes itself evident by a throw of the needle. The fact that a current or magnet when placed near iron exerts a permanent influence on the iron, whereas no such effect is produced on copper or non-magnetic bodies, always seemed to him a marvellous difference. As regards the President's remark that Poisson's theory gave no hint of hysteresis, this he thought was open to question, for the theory refers to coercive force, and this is hysteresis under another name. Coming to the subject of recalescence, Sir William said this was of immense importance, and one of the wonders duly accentuated by the President. In this connection he wished to add that most of the work on the latent heat of iron about the temperature at which recalescence occurs, had been done by the President himself. The region about the ripple in Fig. 13 requires further investigation, and if possible a cycle such as Andrews used in his experiments on evaporation and condensation should be devised. The material exists in two or more different states at the same temperature, and if the effect is reversible, then the iron should cool whilst heat is being supplied to it. In conclusion, Sir William suggested that several physical properties of the material should be tested statically whilst it was kept at temperatures little above and little below the critical one, and also during the various states in which the material exists at the same temperature.

Prof. EWING said he was glad to congratulate the Society on being favoured with such a valuable address, for he was sure that it had been no less interesting to those little acquainted with the subject, than to those familiar with recent researches. He himself was particularly interested in the matter, and was surprised that all the facts relating to magnetisation had been so clearly stated without using the word "susceptibility" or the expression "intensity of magnetisation." Commenting on the enormous amount of hysteresis exhibited by the alloy of nickel and iron (Fig. 11), Prof. Ewing said he had looked for hysteresis in similar alloys and found none; now he saw why he found none, for his experiments were made between ordinary atmospheric temperatures and 212° F., whilst Dr. Hopkinson by increasing the range of temperature had passed the critical points and shown the hysteresis to be very great. One other point he wished to mention in connection with a probable instability which exists when iron is subjected to small magnetising forces. Take the ordinary curve of magnetisation: this may be divided into three portions, O A, A B, B C (*see* Figure). The part O A had been shown by Lord Rayleigh to be a straight line, and he (the speaker) found that in a true magnetisation curve where the condition of endlessness was perfectly satisfied, the part A B should be vertical, or nearly so. His own experiments were made on rods from 300 to 400 diameters long, and on treating these mathematically as ellipsoids, he found that the magnetising force H should be measured from a line, O D, which is practically parallel to A B. A similar result had quite recently been obtained by Mr. Nagaroka, who, in some experiments on the magnetisation of nickel when subjected to mechanical stresses, had succeeded in lengthening the part O A



considerably, and then found A B to be practically vertical. In his own (Prof. Ewing's) experiments on iron he found that by tapping a rod whilst subjected to magnetising force, a permeability of 20,000 could be obtained.

The discussion was adjourned until the 23rd instant.

MEETINGS OF SCIENTIFIC SOCIETIES, &c.

(To-night) FRIDAY, January 24th.

ROYAL INSTITUTION.

9 p.m. Lecture: "The Scientific Work of Joule." By Prof. DEWAR, F.R.S.

MONDAY, January 27th.

LONDON CHAMBER OF COMMERCE.

3:30 p.m. Meeting of the Electrical Trades Committee.

LONDON INSTITUTION.

5 p.m. Lecture, "Electrical Forces." By Prof. A. W. RÜCKER, F.R.S.

SOCIETY OF ARTS.

8 p.m. CANTOR LECTURE II. 2. "The Electro-Magnet." By Prof. S. P. THOMPSON, D.Sc.

TUESDAY, January 28th.

INSTITUTION OF CIVIL ENGINEERS.

8 p.m. Ordinary Meeting. Paper to be further discussed, "Recent Dock Extensions at Liverpool." By GEORGE F. LYSTER, M.Inst.C.E. Paper to be read (time permitting), "Bars at the Mouths of Tidal Estuaries." By W. H. WHEELER, M.Inst.C.E.

WEDNESDAY, January 29th.

INSTITUTION OF MECHANICAL ENGINEERS.

7:30 p.m. Annual General Meeting. Papers to be read (as far as time permits), "On the Compounding of Locomotives Burning Petroleum Refuse in Russia." By THOMAS URQUHART. "On the Burning of Colonial Coal in the Locomotives of the Cape Government Railways." By MICHAEL STEPHENS. "On the Mechanical Appliances Employed in the Manufacture and Storage of Oxygen." By KENNETH S. MURRAY.

SOCIETY OF ARTS.

8 p.m. Ordinary Meeting. Paper to be read, "The Utilisation of Blast-Furnace Slag." By GILBERT REDGRAVE.

OLD STUDENTS' ASSOCIATION.

8 p.m. Special General Meeting at the Central Institution, Exhibition-road.

THURSDAY, January 30th.

INSTITUTION OF MECHANICAL ENGINEERS.

7:30 p.m. Annual General Meeting.

The Electrician.

Published every Friday. Price Fourpence; Post Free, Fourpence Halfpenny
Editorial, Publishing and Printing Offices:

No. 1, SALISBURY COURT, FLEET STREET, LONDON, E.C.

Telephone No. 2714. Telegrams: "ELECTRICIAN NEWSPAPER, LONDON."

All Communications to be addressed to "THE ELECTRICIAN," *1, Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to* "THE ELECTRICIAN."

All letters intended for insertion in "THE ELECTRICIAN," *or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

"THE ELECTRICIAN" *is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.*

"THE ELECTRICIAN" *is on sale at the railway bookstalls throughout the United Kingdom on Friday morning, and can be obtained of all Booksellers and Newsvendors; or direct from the Publishing Offices as above.*

SPECIAL NOTICE.

Owing to the increase in the number of pages of "THE ELECTRICIAN," in order to partly cover the increased postage, we have been compelled to revise the rates for Foreign Subscriptions, which are now as follows:—

	3 months.	6 months.	12 months
For Foreign Parts and Colonies:—	s. d.	s. d.	s. d.
Within Postal Union	6 6	12 6	24 0
Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7 6	14 6	28 0
The rates for the United Kingdom remain as follows:—	5 0	10 0	19 6

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to the office.

TRADE ADVERTISEMENTS *intended for the current issue must be handed in not later than First Post on Thursday morning.*

SMALL PREPAID ADVERTISEMENTS *(for Rates see page xiii.) are accepted up to 4:30 p.m. on Thursday.*

TECHNICAL PRINTING.

"THE ELECTRICIAN" PRINTING AND PUBLISHING COMPANY (LIMITED) *beg to inform Electricians, Electric Light Engineers, &c., that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

"THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK.

Royal 8vo.

Early in each year is issued "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1889 Edition consisted of more than 600 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with popularly-written Biographical Notices of the leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

The issue for 1890, which will be still further enlarged and improved, is in active preparation, and will shortly be ready. Orders should be forwarded at once to the Publishing Office, **1,** *Salisbury-court, Fleet-street, London, E.C.*

OVERHEAD WIRES AND THE ELECTRIC LIGHT.

The effects of the panic in New York are beginning to be felt in this country, and we are saved the spectacle of electric lighting wires being chopped down wholesale only by reason of the fact that there are none worth mentioning to chop down. A case, however, will be within the recollection of our readers where the local authorities having arranged an electric lighting contract on the basis of overhead wires, were subsequently ready to pay 30 per cent. more per annum for the light in order to have the wires underground. This is a long way behind the example of New York, where the axemen's crusade has reduced the Empire City to semi-darkness; but it is near enough, and reports from several of our provincial towns seem to indicate that what happened at Bath will be repeated, though not perhaps in quite so satisfactory a manner for the contractors, in several provincial towns. From Weybridge we hear that there is great dissatisfaction with the overhead electric lighting wires. At Exeter the local electric lighting company is threatened with a prohibition of any further extension of its wires; and at Dundee the consent of the Police Commission for the erection of a single electric lighting wire has been positively refused. Several other places we could name are taking, or are about to take, a similar course; and at none of them can the excuse be put forward that they are so densely populated, or so crowded with traffic, as to render overhead wires, if properly erected, a public danger. The case of Glasgow is somewhat different; but even there we can hardly be expected to endorse what the Corporation has just been

Digitized by Google

induced to affirm, namely, that the 3½ miles of overhead electric lighting wires and cables in that city constitute "a serious risk to life and property."

These may be called the destructive effects of the New York panic: its obstructive effects are likely to be far more serious and widespread. Wherever there existed a local feeling against the introduction of the new illuminant, either on æsthetic grounds or by reason of the commercial jealousy of the gas proprietors, the sinister stories about fatalities due to the electric current, and the heroic remedies which had been adopted in New York to prevent them in future, have been seized with avidity, and employed as missiles to drive all electric lighting promoters off the ground. Five or six weeks ago their prospects were more hopeful than they had ever been; to-day they are clouded by a compact mass of prejudice which it will be hard to clear away, even with the powerful assistance of the Board of Trade. Happily the Board is not likely to slacken in its duty out of respect for a foolish and mistaken popular outcry. The most that the Board can concede in that direction will be to make more stringent the regulations with regard to electric light and power-conductors in general. No one can complain of this; and, indeed, the more rigorous the safeguards are made, the more quickly will public fears be dispelled. Meanwhile, it may be hoped that undertakers who have in hand Provisional Orders or Licences for electric lighting will not allow them to be snuffed out by anything less than a Parliamentary extinguisher.

At this juncture the history of the agitation which has given rise to these troubles may be studied with advantage. It should be remembered that the clamour for the removal of overhead wires in the streets of New York arose in the first instance not so much because of the dangerous currents, but rather because of the unsightliness of the wires, and their well-known insecurity. They had been hastily run up in obedience to a sudden and tremendous demand for the electric light; and being indiscriminately strung together with telephone and telegraph wires, and in the worst manner possible, they were constantly tumbling into the streets, or coming in contact with their neighbours. An outcry soon arose, and as it happened to suit the municipal and political parties then in power, an order for the removal of all wires to underground conduits was easily obtained. A Commission, called the Board of Electrical Control, was appointed to carry this decision through; and as—to quote from a New York contemporary—it consisted of "a political hack, a theatrical lawyer, and a presumptuous young attorney," its essays in the construction of underground conduits were just what might have been expected. The companies, with few exceptions, hung back from putting their property in such receptacles, and the work of the Board was threatened with being left waste and empty. Meanwhile a fresh ally was found in the trade jealousies of the rival electric companies, one of whom started, or at all events encouraged, a well got-up conspiracy to frighten the public into using none but the "harmless" current, which is that company's speciality. The press lent itself to, or was deluded by, this fiction; and in a very short space of time every accident that happened in the streets of New York was indisputably traced to the employment of high-tension and alternating currents. Some of the cases may have been genuine, and no wonder, considering the way in which the wires had been erected; but it was as senseless to attribute the fatalities to the current as it would be to attribute a boiler explosion to the steam when the boiler was known to be rotten. Nevertheless the ruse was successful, and, again to quote from a New York authority, 'the City has accomplished the feat, after four years' trial, of regulating a great industry by destroying it."

It is generally agreed on the other side of the Atlantic that electric lighting conductors of every kind must eventually be placed underground; but nobody at present seems to see how it is to be done, for none of the experiments tried so far on a considerable scale have proved wholly satisfactory. In the meantime the opinion is gaining ground that it would be comparatively easy to devise an overhead, or above-ground, system that would be unexceptionable both to eyes and nerves; and we can see no reason why such should not be allowed in many instances. As to their unsightliness they should be kept out of view as much as possible by running them over housetops, or, as in many cases would be practicable, along the sides of the buildings on suitable brackets, crossing the thoroughfares only at right angles and at suitable heights. Warned of the objections that are likely to be raised, the companies must respect, and not recklessly provoke them, as some of the telephone companies have done. The safety of the wires is a problem of still easier solution. Conscientiously done, the work need give no grounds for apprehension either from risk of fire, breakage on to the streets, or contact with human beings. The experience of the London Electric Supply Corporation is sufficient proof of this, although their system does not in all respects come up to our ideal. Only one serious accident has occurred in connection with this company's wires, and that by no means conclusively traceable to the electric current. We are rather more sanguine than our American friends about the success of the underground experiments which are now about to be tried in London; but it is evident that only in large towns can underground systems be constructed at all. In the small towns, which are just now loudest in their denunciation of the overhead system, they will have to accept that system or none; for it would never pay to put down an underground system to supply a few hundred lights. There are ways of doing the overhead work, however, that would be at once inoffensive, inexpensive, and safe; and electric lighting undertakers will be wise to take the utmost pains to conciliate public opinion on these points.

REVIEWS.

The Law Relating to Electric Lighting. By G. Spencer Bower and Walter Webb. Second Edition. (London: Sampson Low Marston, Searle, and Rivington.)

The authors of this volume, in qualifying for their task, have not confined themselves merely to a careful study of the documents which contain the law on the subject. They let the reader behind the scenes by recording and commenting upon the events which have led up to these documents, and particularly the long inquiry held by Major Marindin last year, and his report thereon. The introduction gives a general survey of these events, and also summarises the salient features of electric lighting law as it now stands, comparing the various methods under which parliamentary powers may be obtained, namely, by Licence, Provisional Order, or Special Act. The law is afterwards exhaustively dealt with in a commentary interwoven between the sections of the Act of 1882. Something has, we think, been sacrificed to the arrangement adopted. It was, perhaps, convenient in some respects to treat the sections of the Act of 1888 simultaneously with those most akin to them in the earlier Act, but owing to these sections being sprinkled about in various parts of the book without regard to serial order, it is rather difficult to find any particular section wanted. To a person who has set himself to read the book through (and it is well worth reading by anyone who desires to gain a full knowledge of the subject), this objection is of little consequence, but as a book of reference it would have been much more convenient to have printed the sections of the Act of 1888 in their proper order. An Act of Parliament may not be

Digitized by Google

very attractive reading, but if you want to know exactly what is and what is not in it, the quickest way is to read the Act through and refer to the Commentary afterwards for explanations. The Model Form of Provisional Order is printed in an appendix, together with the rules issued by the Board of Trade defining the practice on applications for licences and Provisional Orders, and the regulations issued under the Act of 1888, which principally relate to overhead wires used by persons who are not "undertakers" in terms of the Acts.

The most important parts of the Commentary fall under Sections 3, 4, 6, and 10 of the Act of 1882. It is under the first three of these that the powers of the Board of Trade mostly arise, and in pursuance whereof they have issued the rules above referred to, and have also framed the Model Order. Section 10 is described as giving the general rule as to the powers of undertakers, on which the greater part of the remainder of the Act states special limitations. The principles determining the validity of bye-laws which the local authority, with the sanction of the Board of Trade, have power to make, are fully discussed, as also under Section 17 are those which ascertain the liability of undertakers to make compensation for damage done or injury committed by them, and to injunction for causing a nuisance. The list of legal decisions collected under these headings, and the remarks thereon, will be valuable to lawyers, though perhaps of less interest to lay readers.

A useful warning is given on the subject of amendments in Bills before Parliament, which are sometimes inserted by zealous members without a clear idea as to their legal effect. In cases where the law does not allow a thing to be done which some people would like to be able to do, they will get no nearer to it by putting a clause in an Act of Parliament such as the following: "Provided always that so-and-so may not be done without the consent of the Board of Trade." If there is no power to do so-and-so, the consent of the Board of Trade will not give it, and if the power should afterwards be obtained the effect of this well-meant proviso might only be to preclude the power being exercised without the consent of the Board of Trade. Words of this kind were tacked on by amendment at the end of Section 11 of the Act of 1882, following a statement (no doubt quite an unnecessary one) of what is and was then perfectly well-settled law, namely, that Parliamentary powers and obligations cannot be got rid of by merely assigning them to others. It is pointed out that the effect of this amendment is exactly the reverse of what its framers intended.

One of the most important instances in which the Model Order has superseded impracticable provisions in the Act of 1882 is remarked upon under Section 18. That section baldly enacts that any person shall be entitled to a supply of electricity on the same terms as any other person in the same part of the undertakers' area is entitled under similar circumstances. The Model Order restricts the obligation of undertakers to lay mains and service lines at the bidding of private consumers to cases where the latter will secure payment for three years of a revenue from such new works amounting to at least 20 per cent. per annum on the outlay. It also clearly reserves to undertakers the right to make special terms with particular customers as to charges for supply, which are not to affect the ordinary charges to the public.

The authors have in a good many places made incidental reference to various technical matters. Here they have not been so happy, and in most cases have fallen into some error. For instance, it is assumed throughout that high-tension currents must necessarily involve the use of alternate-current transformers. A safety fuse would hardly satisfy the vigilance of Mr. Heaphy, if it would only operate "when a potential dangerous to life is attained"; and undertakers who supply under a storage system would be surprised to learn that they "should never place the batteries in series." The authors are shocked that electricity should ever have been treated as matter capable of cubical measurement, but they have not improved much upon this by describing it as "a force or mode of motion." These, however, are details not in any way material to the general subject, and we only call attention to them with the desire that they may be either omitted or corrected in future editions, which we have no doubt will be called for, with further alterations in the law.

THE DISTRIBUTION OF ELECTRICAL ENERGY OVER EXTENDED AREAS IN MINES.*

BY ALBION T. SNELL, ASSOC.M.INST.C.E.

Some three months ago the writer read a Paper before the Lancashire Branch of the National Association of Colliery Managers at Wigan (*Electrician*, October 25, 1889). The subject then chosen was practically the same as that under consideration now, but it was only treated in an elementary manner, and, moreover, the distribution of energy over extended areas was not discussed. The following Paper is an attempt to give a solution of the problem, in sufficiently general terms, to cover the range of work likely to occur in ordinary mining practice.† At Wigan, the writer felt that electricity as a motive power in mining operations was not properly appreciated by the majority of mining engineers. The subject was but little understood, and very vague notions existed as to the use and possible limits of electrical plant. An effort was therefore made to describe in a crude manner the application of electricity to the transmission of power, and electricity was roughly defined as a means by which energy could be transmitted from a place where it could be cheaply generated to a place where it could be usefully spent. An electrical plant was discussed in its essential details, and its component parts compared with their analogues in a compressed air system. Some plants, illustrative of every-day mining work, were described in detail, and exhaustive efficiency tests were given. The greater part of the Paper was of an elementary character.

Since then, however, the subject has received considerable attention in mining circles, and favourable expressions of opinion have been given by prominent engineers. The results obtained in pumping and hauling at St. John's Colliery, Normanton, and in numerous other pits in Great Britain, Germany, France, and America have at last been recognised as commercial successes. And it may now be fairly assumed that electricity is one of the recognised means of transmitting power in mines. The writer thus feels justified in carrying the subject a stage farther. He proposes to examine the different methods by which electricity can be applied to mining operations on a large scale. For it is evident that, if electricity is to be applied to general purposes, so as to thoroughly compete with compressed air systems, the power must be distributed in such a way that a number of motors can be supplied off the main cables. With the single exception of the dip-pumps at Andrew's House Pit (Wigan Paper), no attempt has been made in Great Britain to lay out for underground work a parallel-motor system, *i.e.*, one in which a number of suitable motors can be coupled at pleasure to the mains, without reference to each other or to the source of supply. (Since writing this Paper arrangements have been made to extend the plant at St. John's Colliery. The addition will be made with a view of a complete parallel system in the future.) This is so, not on account of any electrical difficulty, but simply from commercial considerations. The cautious conservatism of which the British as a race are justly proud has usually limited the installations to a single motor and the necessary dynamo. Hence the electrical engineers have chosen the cheapest and most suitable method of design for a single plant, viz., a series-wound dynamo and motor. This arrangement gives, in addition to simplicity, the important property of nearly constant speed of the motor, if the dynamo be kept running at a uniform rate. This elementary system of installation has done yeoman service in the past, and will still be of use for isolated plants; but the time has come when a more general solution of the problem of electrical distribution in mines is required. Fortunately, there is no need of special experimenting in this direction. The experience gained *above ground* in the supply of power by electric motors is sufficient to satisfy the most exacting conditions of *underground* work. And it is only necessary to modify the methods hitherto used to suit the new conditions.

Electrical distribution of power is accomplished in two distinct ways. The first is made by a continuous current. The second is made by alternating currents. Hitherto transmission of power has, with a few exceptions, only been accomplished commercially by continuous currents. The writer will therefore first discuss the systems involving direct currents. These methods are in general use, and may be distinguished under the following heads:—

1. *Single transmission* by series-wound dynamo and motor. Both C and E are variable.

2. *Constant current transmission*, applicable usually to one dynamo and a number of motors, all running in series with each other. C is constant and E variable.

3. *Constant potential transmission*, comprising in its simplest form one shunt or compound-wound dynamo, and a number of

* Abstract of a Paper read before the Federated Institution of Mining Engineers of Great Britain, Sheffield, January 22, 1890.

† In order to make the subject clear to mining engineers, the effects of induction and the reaction of the armature on the field magnetism are neglected.

Digitized by Google

series, shunt or compound-wound motors. E is constant and C variable.

To properly understand these methods of distribution, which are likely to obtain in the immediate future of electrical distribution of power in mines, it will be necessary to distinguish between the different types of machines, and to understand the characteristics of each system of winding.

The *series winding* is chiefly applicable to a pair of machines. It is most useful where the motor shaft is required to run at a constant speed irrespective of the load. This winding also gives the greatest possible torque or turning moment at starting. These are most important points in many cases, notably the pumping and hauling plant at St. John's Colliery (Wigan Paper), in which the motors have to start against the load of the column and the weight on the two ropes, and also have to maintain approximately the same speed whether the hauling ropes are on or not. With the series system, two or more pairs of machines may be coupled to the same work mechanically, but the electrical connections must be independent. The Normanton plant is arranged in this manner. The two dynamos are driven off the same engine, and the motors are coupled by belts to a common shaft, but each pair of machines are connected by a separate cable.

The *shunt-winding* is adapted for giving a fairly constant difference of potential or electromotive force with a varying current.* It is consequently suitable for a dynamo which has to supply a number of motors running independently of each other, with or without varying loads. If the motors are to run at fairly constant speed with varying loads on such a circuit, they must also be wound in shunt. If they are required to work with a constant torque, say, pump-driving, a series winding may be used with advantage. The "Andrews House" installation is arranged in this way. The dynamo is shunt-wound and the motors are series-wound. It is practically impossible with the shunt system to maintain a constant difference of potential at any given point—a matter oftentimes of no little importance. Every variation of load means a difference in the quantity of current flowing in the main cables; and although the dynamo may maintain practically the same electromotive force at its terminals, yet, since the number of volts lost in the cables is proportional to the current, the tension at any given point must vary directly as the current difference. And since the speed of a series-motor running with a constant torque is directly proportional to the electromotive force of supply, this variation of tension means a corresponding difference in the motor speeds. If a shunt-motor be used the speed will not vary so fast as the electromotive force, but yet the speed is roughly proportional to the tension. Thus, supposing we have a shunt-dynamo on the pit-top giving 250 volts at its terminals and supplying motors at various parts of a mine with, say, a maximum current of 100 amperes, distributed according to the work as in Fig. 5, and let the cable resistance to the first distributing centre be ·25 of an ohm, then the number of volts lost under these conditions up to this point will be = C R = 100 × ·25 = 25 0. The speed of the motors neglecting further loss in sub-mains (and other disturbing influences) will be proportional to 250 – 25 = 225 volts. Now assume that one-half the work be taken off, and the current required be only 50 amperes, the tension at the distributing box will be now—

$$\begin{aligned} E - C R &= 250 - 50 \times \cdot 25 \\ &= 250 - 12 \cdot 5 \\ &= 237 \cdot 5 \text{ volts,} \end{aligned}$$

and the speed of the motors will be roughly proportional to this figure, viz., 237·5, or, the speed will be increased in the ratio of

$$\frac{237 \cdot 5}{225} \text{ or 5 per cent. approximate.}$$

This is not a very serious alteration of speed, but in practice the motors at the extremities of the system would be affected to, say, 15 per cent., or even 20 per cent., through other losses. This shunt-winding is not adapted for motors which have to start against a very heavy load, since the torque they can exert, when run off a series dynamo, is a minimum when they are at rest. You will remember the series-winding under the same conditions gives a maximum torque. If a shunt motor be driven by a shunt dynamo the torque at starting is theoretically a maximum, *i.e.*, assuming the value of the electromotive force of supply is maintained. Practically the tension always falls when the circuit is closed, and it may be so much as to prevent the motor from starting on full load. The ideal method of winding the dynamos for a general system of distributing power is a combination of the series and shunt methods. It is called *compound-winding*. The chief advantage of this winding over the pure shunt is that the ratio of series and shunt effects can be arranged to give an approximate constant difference of potential at a point distant from the dynamo terminals, such as the distributing box in Fig. 5. A dynamo thus wound is said to be over-compounded. An approximation to this regulation can be made by using large shunt dynamos and very heavy copper mains; but, probably, for most cases of mining work, the compound-winding will be preferred, since smaller mains can be used.

* In practice, the terminal E.M.F. will vary about 10 per cent. to 15 per cent. at least between no load and full output.

Characteristic Curves of Dynamos.

The writer thinks that an explanation of the "characteristic curves" of the different types of machines referred to will be only a logical conclusion to the preceding general statements, since without some knowledge of the properties of dynamos and motors a proper appreciation of the capabilities of electrical machinery is impossible. On inspecting the curve of a series machine, it is apparent that the output of the dynamo is strictly proportional to the work required. There is no waste of energy when running light. Assume a load on the motor requiring 20 amperes, the number of volts corresponding is 275, or an output of 5,500 watts = 7·4 horse-power nearly. Now let the torque increase to 50 amperes, the volts will be 425, the watts 21,250, and the horse-power 28·5. If the load be *nil*—that is, if the circuit be opened—the amperes and volts are *nil*, and consequently the output is also *nil*. This is a most important feature in electrical transmission, and is one of the reasons why the coal consumption is always small with a well-designed plant. The series type of dynamo is only used to drive one motor, also series-wound. The chief point to note with regard to the external characteristic of a shunt-wound dynamo, running at constant speed, is the large possible variation of current for a relatively small difference in the value of the terminal electromotive force. Hence, a number of motors could be run off such a dynamo, and have their loads varied within wide limits, without largely affecting the speed of each other. It will be noticed that if the load be raised so that the work corresponds to that part of the curve which is vertical, the electromotive force rapidly falls, and if the load be maintained there is risk of the current falling away to zero. This would obtain in practice if the motors were to be overloaded. This explains why a shunt dynamo is not suited for running motors which have to start against heavy loads. (Special arrangements can be made to modify this peculiarity in some degree, such as first exciting the motor field and then closing the armature circuit through a resistance.) The external characteristic of a compound-wound dynamo shows that the electromotive force can be made practically constant throughout the limits of the designed current variation; or, it can be arranged to any desired slope. This is the type of dynamo which, in a properly modified form, the writer believes will be used for supplying power over mines in the immediate future.

Motor Mechanical Characteristics.

Motors have also their characteristics, but they are of less importance to the present subject, and they also require a better

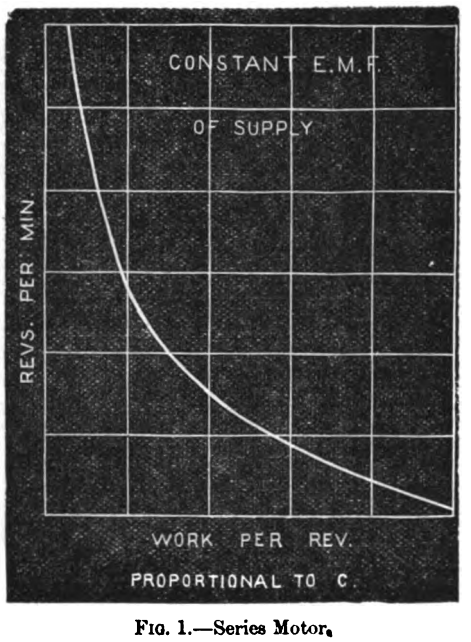

Fig. 1.—Series Motor.

acquaintance with motor work than is assumed here. Reference, however, will be made to what are called "mechanical characteristics," *i.e.*, curves showing the variation of speed for different values of torque or work per revolution.

Fig. 1 shows this relationship in a series-wound motor, supplied with current at constant electromotive force. Note that the work per revolution is a maximum for a minimum speed, *i.e.*, at starting. Fig. 2 gives the result with a shunt-wound motor.

Digitized by Google

Note that the work per revolution varies largely for relatively small differences of speed. If the load were pushed beyond the limiting value of current shown in the diagram, the curve would rapidly drop; but, assuming the potential difference to be maintained at the terminals, the motor would not stop till the current in the armature circuit were equal to the terminal volts divided by the armature resistance. The torque then would not be so great as that possible with a series winding, since the field excitation would be approximately constant through the range of the curve.

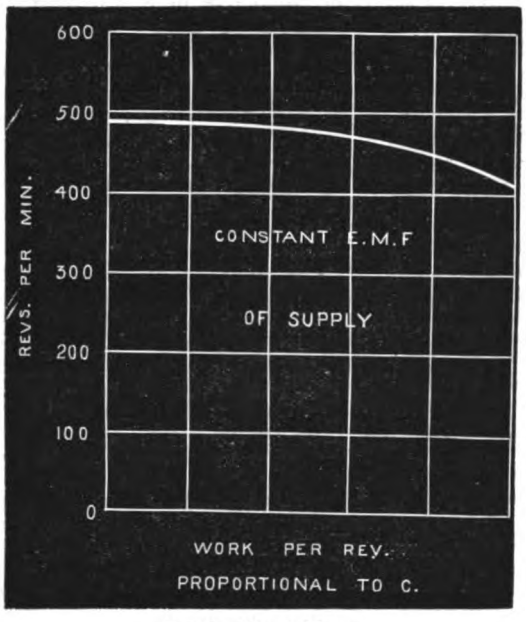

Fig. 2.—Shunt Motor

(Practically it is not possible to maintain the motor terminal electromotive force constant, owing to the fall of potential in the leads. This causes a proportionate weakening of the field as the load increases.) In the series motor both field and armature are temporarily strengthened at starting. Fig. 3 gives the same with a compound-wound motor. Note there are two ways of coupling

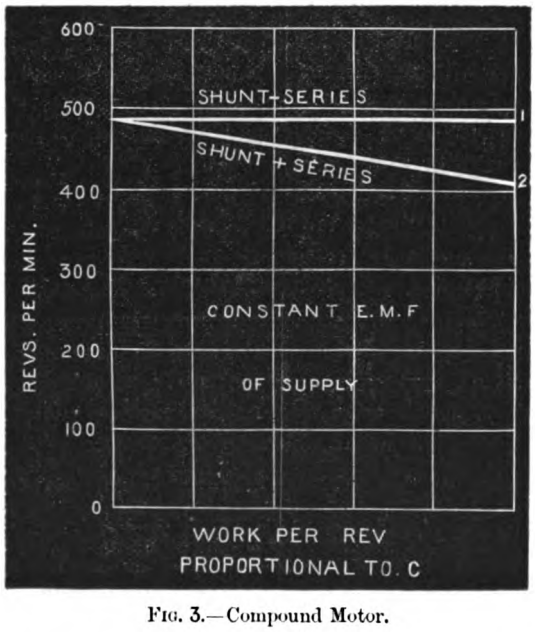

Fig. 3.—Compound Motor.

up the two field windings. In curve I. the windings are differential, *i.e.*, the series coils magnetise the field in the opposite sense to the shunt. This arrangement gives a nearly constant speed throughout the limits of the design. If the machine be overloaded, the series coil is likely to neutralise the shunt effect, and the motor will stop, and may even reverse. This type of motor is thus not adapted for starting against heavy loads, but may be used where regularity of speed is of paramount importance. Sometimes the coils are wound so as to add their effects. The result is shown in Curve II. This winding does not give such a uniform speed as the pure shunt-winding, but since the series-coil is cumulative and not differential the motor will start against a fairly heavy load, and will maintain a speed sufficiently uniform for most purposes between the limits of the design. Some care is required in starting motors of these types. In these three diagrams the abscissæ are proportional to either the current, the torque, or the work per revolution, for these quantities vary together.

Comparing the curves in Figs. 1, 2, and 3, it is evident that with a variable load the shunt and compound-windings are alone admissible, if a fairly good regulation of speed be desired. The series motor when supplied at constant electromotive force is only adapted for a constant load—say a pump or a fan—but is, *par excellence*, the machine for starting very heavy loads, as in hauling plants, with main and tail, or single ropes.

The writer has dipped thus far into the technics of electrical machinery in order to show that the question of the distribution of power by electricity over large areas in mines has been already studied, and presents no insurmountable obstacles to those responsible for the erection of such plants. It will now be convenient to examine a little more in detail the three methods of distributing energy by direct currents, and to summarise the properties of each.

I.—Series-Wound Dynamo and Motor.

Mention has already been made that this arrangement is only suitable for a pair of machines, that the motor exerts a maximum torque at starting, and maintains a nearly constant speed between the limits of the designed load if the dynamo speed be kept

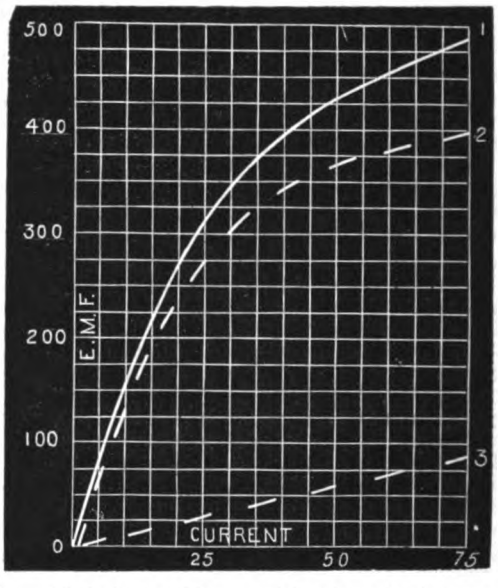

Fig. 4.—Curve 1 is the internal characteristic of a series dynamo running at a constant speed of n revolutions per minute. Curve 2 is the internal characteristic of a series motor designed to be driven by the dynamo. Curve 3 represents geometrically the summation of the resistances of dynamo, motor, and cables. Note that with series machines the field current is the same as the external current.

uniform. It is necessary to refer again to the last-mentioned peculiarity of this system, viz., the constant speed. In Fig. 4, Curve I. shows the variation of electromotive force with the current in a series dynamo running at constant speed; Curve II. shows the same relationship between the electromotive force and current in a series motor designed to be run by the series dynamo; Curve III. shows geometrically the summation of the electric resistance of the dynamo, motor, and cables. Now, Curves I. and II. have been so designed that the difference between any two corresponding ordinates is equal to the numerical value of the same ordinate in Curve III. Also the current in both machines will always be the same, for they form one continuous circuit, and Curves I. and II. were both plotted at constant speeds. Since the difference between them is equal to the electromotive force necessary to overcome the resistance of the entire circuit, it follows, if the dynamo be run at a constant speed, the motor must also run at a constant speed. There will thus be a nearly perfect regulation of the output of energy to meet the demands of the motor, and this energy will be supplied in such a manner as to keep the speed fairly constant. In practice it is not possible to obtain an absolutely constant motor speed; but the regulation can be made sufficiently near for any ordinary purposes. This system is not adapted for electric lighting, either with the lamps in parallel or in series; but a few lamps may be run with suitable precautions.

Digitized by Google

II.—Constant Current Transmission.

In this case, since the value of the current remains the same, variations of power can only be made by directly proportional variations of electromotive force. The system is applicable to any number of dynamos and motors running in series with each other, and is theoretically only limited by the safe working limits of the tension. Since high tensions (several thousand volts) are not likely to be used in mines, there will be no object in discussing this system at length. Briefly, the advantages are a capacity for transmitting energy over very extended areas, where the power is used at widely distant points, with a moderate expenditure of copper in the cables. The chief objection, other than the high tension, is the necessity for a governor of some form to each motor, and probably to the dynamo or dynamos also.

This system, however, is useful in particular cases. The writer has recently designed for Messrs. Immisch and Co. two motors to run on a constant current circuit of 10 amperes and about 2,000 volts. Each motor will develop about 10 B.H.-P. at a speed of 800 revolutions per minute, and will absorb about 1,000 volts. These machines will each run a set of three throw pumps, with 3in. rams of 9in. stroke. Each pump will raise water against a vertical head of about 750ft., making a total lift of 1,500ft., with a 4in. rising main about 1,500ft. long. The dynamo is an arc lamp machine, and will be used for lighting at night and running the motors by day. These motors are fitted with high-speed centrifugal governors which vary the value of a shunt coupled to the field terminals. The speed of the motors for a given torque is adjusted by a spring on the governor. Since the load on the pumps is practically constant, the governing device will only be used in case of accidents, such as a clack getting off its seat, or a failure of the suction. If, however, the load were to be frequently varied, the governors would keep the speed between the arranged limits. There is not much demand for constant-current motors at present, nor does the writer think they are likely to come into general use. They are chiefly adapted to arc lamp circuits, in which they run either in series with some of the lamps, or they are only run by day when lighting is not required. They may also occasionally be chosen to transmit power over very widely distant centres. The constant-current system is only suitable for lighting by lamps run in series, or in multiple series, in the main circuit.

III.—Constant Potential System of Transmission.

The features which make this system the most suitable for general distribution in mines have already been brought out when discussing the characteristics and mechanical curves of dynamos and motors. The pure shunt and the compound-dynamo have also been compared, and the general advantage of the latter shown. Before referring to a practical illustration of this system, the writer will restate the practical properties of the constant potential system with compound dynamos.

1. The dynamo, or dynamos, can be arranged to maintain a constant difference of potential at any desired centre, so as to distribute energy from this centre at the same pressure, no matter how the load may vary within the limit of design.

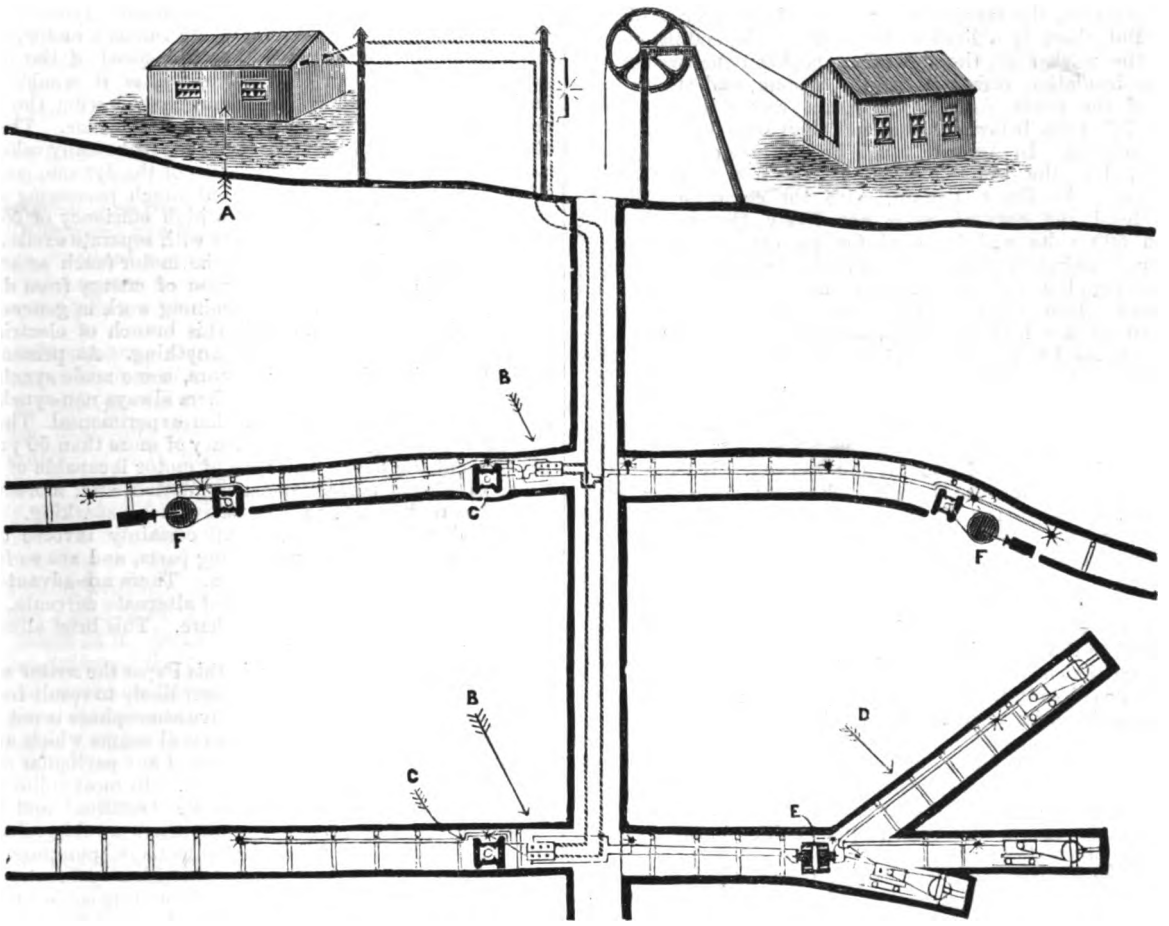

Fig. 5.—Rough Diagram showing a general application of Electrical Power to Mining Operations on the Direct-Current Parallel System, with Transformers.

A is the dynamo-house; B, B, distributing centres; C, C, hauling motors; F, F, pumping motors; E, direct-current transformer; D, rock-drills and coal-cutters. An arc lamp is shown on the pit top, and the stars indicate incandescent lamps at various points in the roads and workings.

2. Either series, shunt, or compound-motors may be used on such a circuit, so as to meet the different requirements of work.

3. A suitable unit size of dynamo being chosen to start with, the plant can at any time be increased by the addition of one or more dynamos. All of these dynamos can be coupled to the omnibus mains, and will deliver electricity in proportion to the required output; just as two or more engines can be coupled to the same shaft, or several compressors can be used to charge a common receiver and service pipe.

4. Various sizes of motors can be run on this circuit if they are wound for the same electromotive force. Thus a 50 horse-power motor can be used for hauling or pumping, a 2 horse-power motor for rock drilling, and a 10 horse-power motor for coal-cutting.

5. Power can be rapidly taken to any part of the pit by running temporary cables from the nearest distributing centre, and any of the motors can be connected. This facility for rapid work in the case of breakdowns, temporary feeders, and perhaps, with

Digitized by Google

certain precautions, sudden outbreaks of gas, will be of marked importance in the near future. Indeed, the electrical distribution of energy by the parallel system has all the flexibility of compressed air, steam, or water systems, with the farther advantage of cheapness, high efficiency, and freedom from bad breakdowns.

6. In case of accident to any part of the system, the damaged cable or machines can be easily disconnected from the mains without affecting the rest of the plant.

7. Incandescent or arc lamps can be run off the mains at any part of the circuit. The parallel system meets equally well the requirements of light or power. The importance of this will be generally admitted.

The chief drawback to the parallel system is the cost of the copper mains, if a relatively low tension of supply be selected so as to run small as well as large motors. The writer proposes the following scheme to meet this difficulty in distributing energy in mines :—

Fig. 5 is a rough diagram indicating the way in which such a general system would be applied. The details, with the exception of the cables, are sufficiently clear. Since the size of the copper for a given transmission of energy depends principally on the amount of current, the tension selected will be usually as high as possible. But there is a limit to the voltage, depending on the extent of the work area, the difference between the sizes of the motors, the insulation resistance of the system, and the general character of the roads, &c. Hitherto the writer has not used more than 725 volts below ground, and then only with separate pairs of machines. In America much higher tensions are sometimes used, but the same restrictions do not apply to the two countries. In Great Britain, with the conditions obtaining, both legal and natural, it is not likely that tensions of more than 500 volts will be used for an extended system of distribution. And even this tension will be too high for serving the motors running rock drills, coal cutters, dip pumps, and auxiliary fans. Indeed, all the larger motors near the pit bottom will be run at the higher voltage, and the smaller and more distant machines by a lower electromotive force. This lower tension will be obtained through transformers, or direct current convertors, as they are sometimes called. These will transform a small current at high pressure to a large current at low pressure. The transformer somewhat resembles a motor with two armatures. It is really a combination of a motor and dynamo. It requires no attention beyond oiling the bearings, keeping clean the commutator, &c., and adjusting the brushes. Since it has practically no strain beyond the torque of the two armatures, the wear is almost negligible in practice. These transformers could be locked up in cabins on the main in-takes. They could be inspected at regular intervals, and could be started or stopped at distributing boxes arranged at suitable spots. Transformers have not yet been used below ground to the writer's knowledge. Their utility, however, is so apparent that he expects to find them in demand before long. Their merit has already been appreciated in more than one general scheme for distribution above ground. By the proposed scheme an economy of copper could be secured in the mains, and the cost of the smaller motors would be lessened. For high tension small motors are not only expensive to wind, but also uncertain as regards insulation. The cost of the sub-mains would be practically the same in any system, because it would not be practicable to use very small or very weakly insulated leads.

The use of an uninsulated *return* is very tempting, since there is plenty of old cable lying about most collieries. The writer has in several cases used iron rope for this purpose with success. But it must be recollected that the risk of possible complications by short circuits would be increased by every additional motor. Considering all things, he does not advise the use of naked returns in cases where more than one or two motors are run off the same dynamo, particularly if the tension be high or the power large. With the system here proposed there would be little objection in most cases to using a naked return on the low-tension circuits, *i.e.*, for the returns to the transformers, assuming the high-tension mains and the dynamos and motors supplied directly from these mains were properly insulated. It is necessary to note that the cost of the transformers and their erection have to be charged against the system. This extra cost will be about £8 per horse-power per transformer. It has to be compared with the saving effected in the copper of the mains, and to the decreased cost of small motors. These two points should alone be sufficient to warrant the arrangement, without reference to the increased flexibility, and the safe use of both large and small motors. It has been proposed to drive low-tension dynamos off the shafts of large pumping motors, and utilise the current to run small motors for rock drills, &c. Immisch and Co. have already made such an arrangement for a Bohemian tin mine. This method is, however, not always applicable, and generally will not be so handy as a transformer system.

Transformers can also be used on constant-current circuits. With such a method of distributing energy the high-tension main current would probably not be used directly to drive motors in most cases, but would be converted into a lower potential current by transformers. These transformers would be placed in suitable centres for distributing power to the motors. The writer did not refer to this under the head of constant-current transmission, because he believes the high-tension current necessary in the primary circuit to be unsuited to ordinary mining practice. There are some cases where, perhaps, this system would be advantageous, but the constant-potential distribution is more likely to be adopted in the immediate future.

Alternate Current Transmission.

This Paper would be incomplete without reference to the second branch of electrical distribution of power referred to under the head of "Alternate Currents." Alternate-current dynamos have been used with great success, but there are several practical difficulties in the construction of efficient self-starting non-synchronous motors, *i.e.*, motors which are both capable of starting against a large torque without extraneous help, and which also can run at speeds bearing no simple ratio to the speeds of the dynamo. Nine years ago it was demonstrated that if two alternate-current dynamos were coupled in series with each other, and both their fields were excited by an independent direct-current dynamo, that if one machine were driven the other would run as a motor, and would do work in an efficient manner ; but the speed of the motor had to synchronise with that of the dynamo, or it would stop, and it could not be started again without first slowing the dynamo and starting the motor by some independent means. Then as soon as the two machines got into step, as it is technically called, the motor would exactly follow all the variation of the dynamo rate of rotation. Such a system of transmission, although possessing a remarkable power of self-regulation, and a high efficiency of conversion, is only adapted to a pair of machines with separate exciters, and necessitates some device for starting the motor (such as accumulators). It may pay in cases of transmission of energy from distant water-power, but is not applicable to mining work in general at present. Rapid strides are being made in this branch of electrical engineering, and it is not safe to predict anything. At present we have a few self-starting alternating motors, some made synchronous after a certain speed is reached, and others always non-synchronous. All of these, however, seem to be rather experimental. The writer does not know of one giving an efficiency of more than 50 per cent. to 60 per cent. at the best. This type of motor is capable of parallel running, of almost perfect speed regulation, and, moreover, in some forms has no brushes, so that there is no sparking. Alternating-current distribution systems will certainly involve transformers. These, however, contain no moving parts, and are so far preferable to the direct-current transformers. There are advantages and also disadvantages attending the use of alternate currents, but it would be inconvenient to discuss them here. This brief allusion must be sufficient for the present.*

In all that has been written in this Paper the writer wishes it to be distinctly understood that the danger likely to result from the use of an unprotected motor in an explosive atmosphere is not glossed over. In metalliferous mines and those coal seams which are free from gas there can, of course, be no need of any particular care in selecting the site of electrical machinery. In most collieries the "in takes" are safe enough, although the "returns" and "faces" may be dangerous. In most of such pits there would probably be little, if any, risk with fixed motors for haulage, pumping, &c., on the main "intakes." For, assuming a sudden outbreak of gas, before the main air-way could be fouled the motors could be stopped, and having once opened the switches all danger from this source would be at an end. There are pits in many parts of the country where naked lights are used in some of the roads and workings, and protected lamps in others. In these, wherever naked lights are used, electrical plant can be employed with equal safety. Speaking generally, wherever naked lights are used, electricity is not dangerous ; and in pits subject to occasional outbursts of gas it can be safely used with due caution and proper ventilation of the motor-house.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

New York, *January* 11, 1890.

The Wire Cutting in New York.—The reign of terror is at an end. Pole-cutting and wire-cutting have ceased for a time. The newspapers find full employment for their sensational powers in writing up "*la grippe*," and the public has recovered its equanimity. The local companies, it is true, have been placed

* It is open to doubt whether an alternating parallel system of distribution can possibly be so efficient as a direct-current system. Certainly, judging from our present standpoint, the plant efficiency of the alternating system will be much less, and consequently the prime cost will be more.

Digitized by Google

in a desperate position; but as an offset to that there is the fact that the time is hastening when the electrical industries of the city will be placed under worthy supervision. The Board of Electrical Control in its annual report shows that up to date the subways constructed in this city represented 73 miles of trench and 1,007 miles of duct, which will accommodate approximately 45,000 miles of telephone and telegraph, and 2,000 miles of electric light wire. At the present time there are 12,308 miles of conductors in the subways, very largely telephonic. It is further claimed that the condition of the subways is in the main satisfactory, and that they are comparatively free from moisture and gas. The report recommends that provision shall be made by which some one department, or official, shall be vested with full power over the whole subject. It is further recommended that instead of attempting to deal simply with the electrical subways, there should be a comprehensive system, including pipes for steam, gas, water, &c. The only inference to be drawn from this last recommendation is, that the subways having now been laid, the Board wishes to pull them up again; for in no other way could such a comprehensive system be arrived at. In the meantime public sentiment in favour of electrical service under proper control is steadily growing, and some of the papers are even anxious to see the restoration of the overhead system.

Standard Rules for Incandescent Wiring.—Considering the great variety of rules for incandescent wiring in this country, I am glad to note that the Council of the American Institute of Electrical Engineers has appointed a committee of members to formulate a standard wiring table. It is not intended to make any radical departure from the best practice of the day, but rather to establish a table which shall be generally recognised.

Dynamo Insurance.—Another interesting proposition, though one that has not yet taken definite shape, is the formation of a company for the insurance of dynamo electric machinery from loss by fire from any source, and especially from accidental short circuiting. It is believed that the standard insurance companies will gladly welcome the establishment of a company for this purpose, and will help it to success, while the local companies should be not less willing to patronise a corporation composed of trustworthy and responsible men, and offering a fair scheme of underwriting. There was a time when the burning out of armatures was a most ordinary occurrence. Even to-day there is far too much of it; but the improvement in construction has been so great during the last year or two, and the manufacturing companies are manifesting such marked improvement in this direction, that it seems reasonable to believe that the burnouts may now be figured down very closely, and to an average small percentage.

Electricity in China.—At the present time electricians are following with a good deal of interest the movements of two Chinese capitalists, who are now travelling about this country inspecting the different electric light systems. These Celestials represent a Chinese syndicate, which are understood to have a 90 years' contract for putting electric light apparatus in the principal cities of the empire. They have recently been the guests of Mr. Westinghouse, and it is said that they have already secured a large quantity of alternating current apparatus, the first plant of which will be set up at Canton, their headquarters. American electricians and workmen will accompany the apparatus and see to its installation and its running for a time. When interviewed on the subject a short time ago, and informed that the alternating current might occasionally kill a man, and was therefore objectionable, one of the Chinamen is reported to have said that he did not see what that had to do with the case, particularly as there was great need in China for better lighted streets, and they could easily spare a man or two as a victim to the scientific progress of the age.

Tesla Motors for Mining Purposes.—Referring to the alternating current apparatus reminds me of the fact that the Westinghouse Company has now entered the field of supplying electrical machines for mining purposes. You will remember that in my last letter I spoke of the imminent boom in this direction, and there is every prospect that the output of electrical apparatus for mining operations during 1890 will be very large. The Westinghouse Company has just secured a very large contract from the Hercules Mining Machine Company of Pittsburgh for a large quantity of generators and Tesla motors. As far as I am aware, this is the first time that alternating motors have been mentioned in connection with any such work, or with any heavy work at all. The apparatus will be used in operating the Hercules coal-mining machines, just lately brought out.

Opposition of the Telephone Companies to Electric Traction.—Owing to the remarkable mildness and openness of the winter up to the present time, electric railway work has been prosecuted briskly, not only in the Southern States, but in the Northern, and a large number of new roads are to go into operation or have just started. A notable feature of the more recent developments in this field has been the opposition displayed by the telephone companies, on the ground that the induction from the power lines has greatly interfered with the efficiency of their service, while the direct contact of a falling line with the railway circuits leads to a burning out, and involves a constant danger of fire. The electric railway men have been very much nettled by this opposition, which arises, they claim, from the idea of the telephone people that they not only own the earth, but the air too; and in more than one place the fight has been quite a hot one, involving litigation. In other places, where the telephone men have been wiser and have recognised the fact that the electric railway is a success, and is here to stay, there has been a compromise in one form or another, and in some instances the railway has borne part of the expense of changing the telephone service from a grounded to a metallic system. One of the most bitterly-contested franchises in the New England States has been that just granted at Lowell, Mass., where, after many hearings and long months waiting, the Board of Aldermen has granted permission to the local street railway company to erect poles, string wires, and use a single trolley system. The franchise is granted under various restrictive conditions as to the construction of the road and the service, and shows that even in Lowell, which has always been a centre of strong telephonic influence, the claims of the electric railway to favourable consideration as a new and important public convenience are fully recognised.

CORRESPONDENCE.

ADVANCES IN MAGNETISM.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: As one having to deal frequently with the magnetic problems presented by dynamo construction, I must take exception to some of the remarks in your leader of last week. You say that "for the sake of the practical men already familiar with the law of Ohm, it is a pity that Dr. Hopkinson has not frankly used the term magnetic resistance of the circuit, but has left it in its reciprocal form as conducting power." Strange as it may appear, my impression was just the reverse of this, for I thought that one of the most praiseworthy features of the Presidential Address was the omission from it of the term magnetic resistance.

It is true that the early experimenters in groping for the relation between magnetising force and induction employed the term magnetic resistance, because, for a low induction the ratio $\frac{H}{B}$ is a constant, like $\frac{E}{C}$ for an electrical circuit. But this is not the law of the electro-magnet, and the analogy here presented is of the most superficial character. For a given electrical circuit the current is expressed as the simplest function of the E.M.F.; for a magnetic circuit, the induction is a function of the magnetising force, but of so complicated a character that its expression has hitherto defied formulæ, and graphical treatment must be resorted to. Always dangerous, analogies are only to be tolerated if they prove helpful; but here, in consequence of the fictitious colouring it gives to a particular group of phenomena, the term *resistance* constitutes an actual difficulty. To its use in a colloquial sense I raise no objection, but I think it high

Digitized by Google

time that its use in a scientific sense should disappear. In the fact that one cannot think of magnetic resistance without thinking of Ohm's law lies the objection, for with thoughts of the latter is associated a group of relations having no bearing on the case.

Freed from association with Ohm's law, *magnetic resistance* might be of service; but as such emancipation is now impossible, it had better disappear as a scientific term. Your "practical men" may be awful dullards, but it is doubtful whether their mental conceptions will be quickened by this false analogy, which might very well be included amongst the other antique notions to which reference is made.—Yours, &c.,

London, January 22, 1890. W. B. Esson.

[In spite of these objections, we think the term magnetic resistance *is* of great service in simplifying the description of the properties of the magnetic circuit. If the expression is so misleading, we fail to see how the matter is improved by using the reciprocal, as our esteemed correspondent seems to imply it is. The remark in our leader was meant chiefly to allude to the need of some term conveying the same idea as magnetic resistance.—Ed. *E.*]

TRANSFORMER DEVICES.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: Would it be possible, and if possible practical, to employ for the purpose of automatically opening and closing the circuit of large transformers, a small auxiliary transformer having its highest efficiency when working on open circuit? It might be arranged somewhat as follows:—A switch with mercury contacts is used, actuated by an electro-magnet in circuit with the secondaries of both transformers. When the secondary (house) circuit is opened, the switch pulled over by a spring completes the connections of the auxiliary transformer, both primary and secondary (street mains and house leads). On closing the house circuit the electro-magnet is excited by the current from auxiliary transformer through house leads and pulls over the switch, thereby opening the circuits of auxiliary transformer and closing those of main transformer. The contacts being so arranged that one set of connection is made before the other is broken, the magnet remains active, and holds over the arm of switch. The connections are rather complicated, but have been worked out in diagram, and seem practical enough—on paper.—Yours, &c., C. D. S.

Aberystwith, January 20, 1890.

[Disconnecting a large transformer from the high potential mains in the manner suggested would, we fear, destroy the insulation of the transformer whose primary circuit is suddenly broken. We suppose the auxiliary transformer mentioned is to work efficiently with light load. If it is to have its highest efficiency on "open circuit," we are afraid the method could not work.—Ed. *E.*]

TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning.*]

Tenders Invited.—The Electrical and Lighting Committee of the Edinburgh International Exhibition, which will be opened in May next, invite tenders for the working of the Electric Railway within the grounds of the Exhibition. The track will be about 1,000 yards in length, and will be laid out so as to be of real utility to visitors in getting from point to point. Further particulars are given on page XIII. of our advertisements, and full information can be obtained of the Secretary, 27, Frederick-street, Edinburgh.

Messrs. Crompton and Co. (Limited).—We have received from this company an advance copy of a handsomely-bound catalogue of their well-known manufactures. The book is admirably illustrated, and gives complete descriptions, price lists, &c., of the widely used Crompton dynamos, arc lamps, projectors, parabolic reflectors, incandescent lamp fittings, both plain and ornamental, ornamental brackets, suspenders, and other artistic fittings. Towards the end of the book are given descriptions of the Crompton measuring instruments and illustrated descriptions of main switch-boards for central station work. A section of the book is devoted to electrical traction and to particulars of the Crompton-Howell accumulators. A very useful feature in the book is a set of specimen estimates for arc lighting plant for ship, factory, town, and private lighting. The catalogue is priced at 10s. 6d., but Messrs. Crompton and Co. inform us that they are issuing a catalogue containing the same text without the special illustrations, and bound in a cheaper style, price half-a-crown. This cheaper edition can be obtained, free of charge by the trade, on application to Messrs. Crompton and Co., who include in "the trade" not only electric light engineers, but all kindred trades and professions, such as architects, civil engineers, builders, merchants, and exporters. The catalogue is not devoted to the description of small electric apparatus, but mainly consists of particulars relating to heavy machinery and principal parts for central stations and large installations.

Messrs. Davey, Paxman, and Co.—About eighteen months ago we mentioned that the great increase in their business had rendered it necessary for Messrs. Davey, Paxman, and Co. to enlarge their works, and that new premises were erected to take the place of the old pattern shop, which was then cleared and added as an extension of the foundry. Increased business is responsible for a still further extension of the works. The present large addition is to the foundry and boiler shops. The good name which Messrs. Davey, Paxman, and Co. have won for themselves by the excellence and good performance of their well-known engines, and the honours and awards taken by them at the various exhibitions held during the last few years (and more especially those gained at the Newcastle and Society of Arts Trials), together with the selection of their engines for doing a large part of the driving at the Paris Exhibition, has no doubt contributed much towards making the present large extension of their works necessary.

Messrs. Felten and Guilleaume.—During the past year the firm of Messrs. Felten and Guilleaume, of Mulheim-on-Rhine, have been actively engaged in the manufacture of iron, steel, bronze, telegraph and telephone wire, and cables for telegraphic, telephonic, and electric light purposes. It is interesting to learn that, after an interval of several years, they have added a new and important link to the network of underground telegraph cables, which renders the German telegraphic system so remarkably safe in the severest storms. During the almost unprecedented snow storm of February 9, 1889, the telegraphic business of Germany was not interfered with in the slightest degree, although in the surrounding countries the telegraphic lines were broken down. The new line is from Karlsruhe to Stuttgart, 50 miles in length, formed of a 7-core cable, the cores being insulated with gutta-percha. This line was finished on November 27th last. The same year has witnessed the opening of the Buenos Ayres-Monte Video telegraphic and telephonic line, which presents many features of interest, mainly on account of a submarine section of 28 miles in length, on either side of which are aerial bronze lines of 70 and 97 miles respectively. This line is constructed on the metallic circuit system, and is used for telegraphy and telephony simultaneously, was opened on October 20th last, and works admirably both with regard to clearness and fulness of sound. No similar line is, as far as we are aware, in existence. It may be further mentioned that Messrs. Felten and Guilleaume have been very busy in manufacturing telephone cables for the German and Foreign Telegraphic Administrations; and although the resources of the firm are very considerable, they have been occupied to the utmost of their power. The same may be stated with regard to electric light cables, which are principally of Messrs. Felten and Guilleaume's impregnated fibre lead-covered type. These cables have worked very satisfactorily in the central lighting stations of Barmen, Hamburg, Bremen, and Lübeck. Owing to the large increase of business, this firm have largely increased their plant for the manufacture of bronze telegraph and telephone wire during the year, and are now producing several new types. Several inter-urban telephone lines in Germany, Austria, Hungary, Sweden, and other countries have been constructed with their bronze wire.

Messrs. C. A. Parsons and Co., Heaton Works, Newcastle.—The new works of this firm, which are conveniently situated near the Heaton station of the North-Eastern Railway, in a suburb of Newcastle-on-Tyne, are now in full operation. They cover more than two acres of ground, and are connected to the railway by a siding to facilitate the delivery and departure of heavy goods. The firm are busy with the manufacture of slow-speed dynamos of several types, in addition to other specialities. They have in hand an extensive order for the Italian Government for a number of large projectors and automatic lamps of improved design for coast defence, and also some large contracts for material for the Newcastle and District Electric Lighting Company. Messrs. Parsons and Co. are now in a position to undertake contracts of any magnitude, and will, we feel sure, have no reason to complain of want of business. The works have been specially built to meet the large demand which exists for high-class electrical machinery.

Digitized by Google

WOODHOUSE AND RAWSON UNITED (LIMITED).—This Company, as is well known, has taken over the business of Woodhouse and Rawson (Limited), the Woodhouse and Rawson Manufacturing Company, and the Woodhouse and Rawson Supply Company, together with other businesses at Manchester and Bradford, and has only been in existence six months. As regards its manufacturing business, we understand the extension has been steady and satisfactory. Mr. Charles Baker, whose business was taken over by this company, being in charge. The old specialities of the firm have been further improved, and the total number produced have been largely in advance of previous years, the turn-out of one size of switch alone being over 1,500 per week. In addition, several specialities have been worked out and acquired, chief among these being a new insulating substance which is just being put upon the market, Scott's electric flashing lantern for signalling purposes, and a new oil filter and sight feed lubricator. Important improvements are, we understand, also being made in incandescent lamps. In the supply department the extension of business has been rapid, and more recently large quantities of goods have been supplied to electrical companies abroad. In common with most electric firms the contract department of Messrs. Woodhouse and Rawson United (Limited) has been very busy, principally on electric lighting work. Police alarms systems, bells, telephones, and plating work have also added their quota to the year's industry. Among the most important lighting contracts carried out are the palace of the Maharajah of Mysore, Lord Ripon's house, &c. This department also executes a considerable amount of maintenance work, including the installations at Drapers' Hall, Exeter Asylum, &c. Contracts for the supply of instruments have been filled with the London and North Western Railway, Caledonian Railway, Manchester, Sheffield and Lincolnshire Railway, National Telephone Company, as well as the Admiralty and other Government departments. The engineering departments have been very busy, especially in the screw-making section, and a large amount of new plant has been laid down to enable the orders in hand to be executed. By the acquisition of the Bradford business, where installation work is very brisk (the company being specially appointed as contractors to the Corporation), the sphere of the company's operations has been considerably extended in the North of England. In the early part of the year the company identified themselves with the Elmore depositing process, a full description of which has appeared in *The Electrician*. Careful experiments were made by the company's electrician which convinced them of the commercial value of the invention. An English company has been formed, and is now commencing work, and the undertaking bids fair to be a decided success. If the process proves to be all that it claims it cannot fail to be one of the most important commercial undertakings allied with electricity. It is rumoured that the application of the same process to another important metal is likely shortly to be announced. This company, which has already declared an interim dividend at the rate of 15 per cent., will, it may fairly be anticipated, continue to progress in the future in the same satisfactory manner as it has in the past.

D. H. BONNELLA.—We are in receipt of a circular announcing that Messrs. Martin and Co., of New Broad-street, E.C., and Mildmay Works, N., have transferred their business of ivory and hardwood turners for electricians, &c., to Mr. D. H. Bonnella, who will carry on business at 58, Mortimer-street, Cavendish-sq., W.

MESSRS. H. BINKO AND CO.—This firm has just issued a neatly got-up catalogue of electric bells, signals, telephones, lightning conductors, fire alarms, medical appliances, &c. Descriptions are given of Binko's patent portable telephone, of the "Dolphin" acoustic mechanical telephone, of the electric Binkograph, of the mechanical railway guard and passenger signal bell, with a number of other special manufactures of this firm. Like most other catalogues now issued by electrical firms, this contains some resistance tables, &c., and complete price lists. A section of the book is devoted to accumulators and fittings for the electric light, dynamos and motors. Several descriptions of portable lamps are illustrated, and a selection of fancy shades, electrical brackets, table lamps, &c. The book contains 116 well-illustrated octavo pages.

MR. ROBERT WOODLEY.—The premises occupied as workshops by Mr. Robert Woodley, electrical engineer, at Clemence-street, Burdett-road, Limehouse, were destroyed by fire on Saturday morning last. The cause of the fire is unknown. We are requested to announce that Mr. Woodley's business will be carried on as usual at the old address, 248, Burdett-road, E.

TUBES AND FITTINGS.—Messrs. J. E. and S. Spencer, of Great St. Thomas Apostle, Cannon-street, inform us that they have reduced their discounts 2½ per cent. less on the gross from wrought-iron tubes and fittings.

THE ELECTRIC LIGHT IN SYDNEY, N.S.W.—In a letter of December 4th Messrs. Wood Brothers and Co. write us:—"It may be interesting for you to know that we are now erecting plant to fulfil a contract we have undertaken to light by electricity the streets and houses of Moss Vale, which is a town 86 miles from Sydney, on the Great Southern Railway, the health-resort of Sydney and the country residence of the Governor of New South Wales, as also of many of the prominent men of the colony. We expect to have the street lights running by Christmas."

"THE YEAR-BOOK OF PHOTOGRAPHY FOR 1890."—Messrs. Piper and Carter, of 5, Furnival-st, Holborn, E.C., send us this very useful annual, containing about 400 pages of all kinds of information concerning the photographic act. A large number of our readers are no doubt interested in photography, and will be glad to know that the 1890 edition is now ready.

"COMMERCIAL LONDON."—We have received from the Intercolonial Publishing Company (Limited) the volume of "Commercial London" for 1890. The book is edited by Mr. Th. Simpson Jones, the editor of the *Eastern, Australasian, and South African Journal of Commerce*, consists of more than 500 pages, and contains a large amount of useful information. It is published at the low price of five shillings.

BOOKS, &c., RECEIVED.

"Annuaire pour l'An, 1890." (Paris: Gauthier-Villars et Fils.)

LEGAL INTELLIGENCE.

United Telephone Company v. Tasker and Sons.

In this case, which came before Mr. Justice Kay in the Chancery Division of the High Court of Justice on Monday, the plaintiff company sought to restrain Messrs. Tasker and Sons from using or selling an instrument which was alleged to be an infringement of the well-known invention of Mr. Graham Bell as applied to telephones.

The Attorney-General, Mr. Aston, Q.C., Mr. Moulton, and Mr. Micklem appeared for the plaintiff company, the defendants being represented by Mr. Renshaw, Q.C., Mr. Bousfield, and Mr. Neill.

Mr. ASTON having briefly opened the case,

Mr. RENSHAW submitted to the injunction asked, to an account, and an inquiry as to damages. He then opened his counter-claim for damages in respect of an agreement alleged by him to have been entered into between the plaintiff company and the defendants, and contained in correspondence which passed between the parties from the years 1879 to 1884. By this agreement the defendants contended that they were authorised by the plaintiffs to establish in Sheffield a telephone exchange, and to promote a local company for that purpose; and, further, that the plaintiffs agreed to supply the defendants at a fixed price with such telephones as might be necessary to carry on the exchange, the defendants to be the sole agents of the plaintiff company for the supply of telephones in Sheffield. Subsequently the plaintiffs provided a rival telephone exchange in Sheffield with telephones, and refused to carry out their agreement with Messrs. Tasker and Sons.

His LORDSHIP, without calling on the plaintiffs, dismissed the counter-claim with costs, holding that the alleged agreement had not been established.

International Cable Company.

A petition, presented by Mr. A. S. Bolton, for the winding-up of this company, was in the paper for hearing before Mr. Justice Stirling on Saturday last.

Mr. GROSVENOR WOODS, who appeared for the petitioner, said he understood the company were desirous that the petition should stand over, and to this he had no objection, provided the company undertook to file their affidavits in opposition by Wednesday. He understood that the company intended to cross-examine the witnesses upon their affidavits.

His LORDSHIP directed that the petition should stand over.

In re James Fyfe.

On Wednesday at the London Bankruptcy Court, Mr. H. Brougham, an assistant receiver, presided at the first meeting of creditors under the failure of James Fyfe, St. Stephen's-chambers, Telegraph-street. The debtor states that he had gross liabilities of about £17,000, due to the fact of the gentlemen who agreed to buy his different patents having failed to carry out their original contracts. Previous to 1884 he was the managing director of the Pilsen-Joel and General Electric Light Company (Limited) but has not had any regular occupation since then. He acted as part promoter of the Ross Oil Lighting Company (Limited) in 1887, but received nothing for those services, the company having gone into liquidation. In July or August, 1888, he bought the patent with all rights of a new electric arc

Digitized by Google

light for £50, subject to a further payment of £600 to be made out of the profits. That patent was sold with all liabilities in August, 1889, for about £480, and he is now working it, jointly with another person, for the purchaser, who provides the necessary capital. He holds an agreement for shares in profits in the Brixton Improvements, a building scheme, of which he was a promoter; also an agreement for shares in profits for lighting the town of Los Palmas, in the Canary Islands, by electricity, of which scheme he was the promoter in England, and expects to receive one-third of the concession price. The debtor further is possessor of certain shares in the Foreign Pilsen Company and the Pilsen-Joel Company, but does not estimate they are of any value beyond the amount charged upon them. No accounts have yet been filed, and the Chairman stated that when the debtor had furnished his statement, in all probability a new meeting of creditors would be convened to deal with the matter. In the absence of any resolution, the matter will remain for the present in the hands of the Official Receiver.

COMPANIES' MEETINGS.

The Eastern Telegraph Company (Limited).

The 35th half-yearly ordinary general meeting of this Company was held on Thursday, January 16, 1890, at Winchester House, Old Broad-street, under the presidency of Sir John Pender, K.C.M.G.

The SECRETARY (Mr. George Draper) read the notice convening the meeting and the minutes of the thirty-fourth half-yearly ordinary general meeting held on July 18, 1889.

The CHAIRMAN, having signed the minutes, and the report being taken as read, said: Gentlemen, I suppose it is not too late in the new year for me to observe the good old Scotch fashion of wishing you a very happy and prosperous new year, not only in regard to this Company, but in regard to all other concerns in which you may be individually engaged. I think I may preface my remarks by saying that the report is a very full one, and if you look at the abstracts connected with that report, you will find that everything is accounted for, and that you have an amount of information given to you which almost, I believe, supplies all the knowledge that we ourselves possess. That has been our policy so far, and we desire that it should be maintained and continued. The gross revenue for the six months ended September 30, 1889, amounted to £351,014, as against £310,104 in the corresponding period of the previous year, showing an increase of £40,910. That is a very handsome increase, gentlemen. About £29,000 of it is derived from messages, and £12,000 from additional dividend on our increased holding in the Eastern and South African Telegraph Company. This is a matter to which I shall refer later on in my remarks. These figures show that the revenue for the past half-year has been exceptionally good, and the Directors hope this improvement will continue. I may mention that the revenue of this Company, as I have very often stated at these meetings, depends in great measure upon the state of the trade of the country. I have often said that the telegraph system is about the best barometer of trade, and I think that this is shown to-day; for while we admit that commercial prosperity has prevailed throughout the world generally, we show that we are participating in the improved state of things. That will always be the case, for I hope I shall show you in my remarks that, after all, the commercial prosperity and progress of this country are closely and immediately identified with the submarine system of telegraphy. The greater part of this increase in our revenue, I may mention, has been caused by the development of business in South Africa, but it is pleasing to note that, with one exception—viz., India—an increase has taken place in all classes of our traffic, owing to the general improvement in trade both at home and abroad. This general prosperity throughout the country affects almost every article which is dealt in by the aid of telegraphy. For instance, coal has largely increased in price, and I learn that such articles as gutta percha, copper, hemp, and iron wire—indeed all materials required for the manufacture of cables—have enormously increased in price. All that is an evidence that there are profits going, and that the general trade of the country cannot be prosperous without our participating in it. The total working expenses for the half-year amounted to £87,730, as against £83,332 in the corresponding period of 1888, or an increase of £4,398. The details of increase and decrease are as follows:—General expenses in London have been £8,411, as against £7,845, or an increase of £566. This is owing to the steady increase of our business requiring more hands, additional accommodation, &c. In other words, we cannot increase our business without increasing the facilities for conducting it. The working expenses at the stations were £64,712, as against £59,962, an increase of £4,750, the principal item of which is for salaries of the additional staff required. The staff has been increased by some 40 additional manipulators at our stations. Each of these young men is paid a fair salary, and therefore if you take that increase in our staff, the amount of increase in the expenditure at the stations is not a very large one. We also considered it expedient to grant some increases of salary to our older *employés*, more particularly the superintendents and clerks at stations. They have done their duty in a thoroughly satisfactory manner, and have, together with the heads of departments in London, had much to do with the building up of this concern, and we must not forget them in the midst of our prosperity. Therefore, when we have something to spare we are always desirous of recognising those who are entitled to our consideration. The repairs to cables amounted to £49,634, as against £43,075 in the same half of the previous year, being an increase of £6,559, full details of which will be found under abstract "C" in the accounts, which is really a very interesting abstract. It shows the expenses of our steamers, and at the same time indicates the improvements that are being made in our property. These steamers go moving about from place to place, conducting repairs in the most silent way. We scarcely hear now of interruptions, and the reason of that is that we have made our system almost as perfect as it is possible to do. But I have often stated on these occasions that a single line of telegraph is not to be relied on. Unless you have a duplicate line you cannot maintain that continuity—you cannot give confidence to merchants who are relying on the telegraphs, and who require confidence in connection with the successful conduct of their operations. Two days ago I saw reported the enormous tonnage of the world—many, many millions of tons—and 75 per cent. of the whole amount is in British bottoms; and when I tell you that, you will see what a solid foundation there is for our submarine system of telegraphy. There is not a ship that does not more or less in the course of the year have to use our system, which, therefore, has the deepest root it can have, and the widest area for expansion of any existing system that I know of in the world. The other day it was considered the great feature of the age in politics, but I say that in commerce it is a greater factor still. We who have been associated with submarine telegraphy from the beginning have every reason to be pleased with the results we have achieved, and with the position that we are in to-day in regard to our dividends. We do not profess to go in for extreme dividends, but we have tried to put by such an amount as will secure not only the present, but build up great security for the future; and as we strengthen our foundations so we shall be able in the future, I hope, to increase our dividends. This is not a yearly, but a half-yearly account. Referring to the speech I made six months ago, I gave you then a very full amount of information, and if I were to repeat it to-day it would show pretty well the position we are now in; but I do not intend to refer to it further than to say this—that the large amount we are carrying forward—over £60,000—will be dealt with at the next half-yearly meeting, and I hope it will be dealt with in such a way as will be satisfactory to those who are interested in it. In that £60,000, I may say there is a satisfactory bonus, and if the next six months are as successful as the past we shall have something to do in that direction. I have given you a certain amount of detail as to the working of this concern. There is one other point that I wish to draw your attention to, and that is in connection with the map that is behind us. This great dark country, as it is called, is now being opened up, and last year we finished the complete circuit of the whole of this dark country—Africa; and I then remarked that this was, I believed, the largest thing that had yet been done in connection with submarine telegraphy. I pointed out to you that the completion of this system involved something like 17,000 miles of cable. No other company could attempt to do anything of the kind. Therefore while other countries are striving hard to get a footing in Africa we are pioneers of the whole thing. We have put ourselves in such a position that at every point of the seaboard we are in communication with the old country. That is a very important position to be placed in; and in referring to those who have more or less benefited us and assisted us in that enterprise I am bound to say that England has done a very great deal. The English-speaking people, you may say, have made Africa up to the present point, and as long as the English tongue and the enterprise which follows it continue, we have a wide field for development in Africa. Portugal has been kind, generous, and liberal to us, whatever may be said of her want of enterprise in the development of her colonies. As far as we are concerned, Portugal has done everything in connecting its colonies with the mother country, and has assisted in every way. France has done the same to some extent, and so has Spain; but, curiously enough, the only country that has not assisted us in any way is Germany. Germany is now trying to get a hold in that country, but I may mention that to get a hold there they find they must do something for submarine telegraphy. We do not connect with many of their ports, but where we do they get all the benefit that other countries receive without having contributed one shilling. I mention this fact, and it may get to the ear of the German Government. Five years ago I drew their attention to it when we were going into our scheme for African extensions. They have, however, been making inquiries, and I hope next time I meet you I shall be able to state that Germany is taking part in the system of submarine telegraphy, which is doing so much good. Our policy generally is, as far as possible, to follow the trade and flag of England. As you are aware, Africa is now in a state of transition. There are two very important companies there—the Imperial British East Africa Company, and the British South Africa Company, both in the hands of bold, intelligent, and large-minded men. There will be rapid development there, and we have, therefore, without hesitation, laid a cable (I believe it is completed to-day) from Zanzibar to Mombassa, the headquarters of the Imperial British East Africa Company. That is a Company working under a Royal Charter. England is the suzerain, and the result will be, I hope, very rapid development. We have, however, done our part, we have followed the flag, and I hope we shall get the benefit from increasing trade in the traffic over that section which we have laid, because it puts them in connection with the whole of the civilised world. That shows you our policy so far. I may now use a phrase which is very often used by greater people than ourselves, that we are on very friendly relations with almost—in fact with every Government of the world. Only the other day our friend the Emperor of Morocco visited Tangiers. He was so opposed to our system at one time that he objected—and strongly objected—to our landing there; but we did so at last, and on the occasion of his visit His Majesty was so pleased with what he saw, that instead of reviling us, he presented us with a site to build an office upon, so that it might be an evidence of his goodwill towards the Company. We consider that a very great compliment to us. Our relations with the Sultan of Zanzibar are very similar. He gives us every possible facility. He has also given us a site and a house for our station, and our relations with him are thoroughly satisfactory. Two days ago we concluded with France agreements which will extend over the next 20 years. They were renewals of agreements that have existed, and which have been thoroughly satisfactory to us, for the last ten or twelve years. Those agreements will give us—what shall I say?—a very strong hold indeed upon the Mediterranean

Digitized by Google

system of telegraphs. We shall be able to run lines from Marseilles to Malta and Algiers. Those arrangements are as satisfactory to France as to us, and to the senders of messages. There is another point which I may mention in reference to this branch of my remarks. I have always tried to impress upon the shareholders that we want this submarine telegraph to have an international character. We cannot work it ourselves as a monopoly. We must work it for the whole world, and the whole world gets the same benefit from it as England does. We have no advantage which any other country does not possess in connection with this system, so that we have a broad field for our work. I find by degrees that the different countries are recognising this, and that on the whole they are very friendly towards us. I have one other subject to bring before you. We have generally received some suggestions and letters from some of our careful proprietors when the meeting of the Company is going to be held; but I think, so far as this meeting is concerned, only one letter has come to hand. It was addressed by a shareholder to Sir James Anderson, who was asked whether the Telegraph Conference that is to be held in Paris this year is likely to reduce our rates, and consequently to interfere with our dividend. The Telegraph Conference was held last at Berlin five years ago, and another conference will be held in Paris this year. But such is our position—such I think is the strength of our position—that we are so useful to all nations, that I do not see well how they can interfere with us, or do us any serious harm. They may want to reduce our rates; but we have this answer to give them: that there is not a Power in Europe whose land telegraph system is earning them a profit. Therefore, we say that it may be very easy for them to reduce their rates if they choose to do so out of the public money, but it would not be fair for them to do anything that will interfere with a Company which is so greatly benefiting them and the world generally. It would not be fair or right to reduce our rates in such a way as seriously to injure the Company, and at the same time practically injure the populations themselves of the countries that will be represented at the Conference. We think our arguments are very strong, and we hope that when the time comes, while we are always willing to deal with things in a fair spirit, our arguments will be such as will enable us to hold our position. Whatever concessions we make shall be made in a direction that will bring increased traffic, and consequently the exchequer will not lose by the concessions. That is the policy we intend to pursue. We have now a little difference of opinion in Egypt. I intend to proceed to that country a few days hence, and I hope my visit will be instrumental in settling this little difference. This I do know, that we have right on our side, and I am always prepared to fight a strong and hard battle as long as we feel that we are not asking anything to which we are not fully entitled. I think that exhausts every point that I need address you upon. I thought when I began to speak that I had said so much six months ago that it would not be necessary to say much on this occasion, but, really, when I begin to talk about submarine telegraphy, I am afraid that I do not know when to stop. I will, however, now move:

"*That the report and accounts of the Directors to September 30, 1889, submitted to this meeting, be and the same are hereby received and adopted.*"

The VICE-CHAIRMAN (the Marquis of Tweeddale): I beg to second that.

The CHAIRMAN: If any gentleman desires to ask any question before I put the motion, I shall be very glad to listen to him. Those in favour of the motion please hold up their hands. To the contrary. Carried unanimously. The next motion is:

"*That George Garden Nicol, Esq., who now retires, be and is hereby re-elected a Director of the Company.*"

Just let me say one word on this motion. It is rather remarkable what I am going to tell you. Mr. George Garden Nicol has been a friend of mine for a longer period than I choose to tell you; but you saw the very laudatory remarks which were made the other day in the *Times* about the enormous prosperity which has attended our colony of Hong Kong. Mr. Garden Nicol, who has been associated with us in all the progress of this great Company, who sits at this Board to-day, was landed at Hong Kong when I suppose there were not a hundred people located on it—long before the British Government took possession of it, and now it has become what I may almost call a model colony of England.

Sir JAMES ANDERSON: I beg to second the motion.

Mr. CLARKSON: I wish to question the expediency of the everlasting system of duplicating and triplicating ——

The CHAIRMAN: I am afraid you are too late. I invited you to speak on the report.

Mr. CLARKSON: You did not give me time.

The CHAIRMAN: I paused some time.

Mr. CLARKSON: No, you put the motion instantaneously.

The CHAIRMAN: If there is anything interesting you have to say, and the shareholders choose to listen ——

Mr. CLARKSON: I do not care whether I stay here three centuries or three months, I am determined to have my say. ("Chair! Chair!")

The CHAIRMAN: I do not want to stop you.

Mr. CLARKSON: Never mind that, I am determined ——

The CHAIRMAN: You are in the hands of the meeting.

Mr. CLARKSON: I am in the hands of myself. I have been a shareholder for 17 years, and I am determined to have my say.

The CHAIRMAN: Will you come forward and say what you have to say?

Mr. CLARKSON: I will say what I have to say here.

The CHAIRMAN: What is your name?

Mr. CLARKSON: Mr. Clarkson.

The CHAIRMAN: I want to conduct this meeting as we have always done before. We have done things in a regular and proper way. If it is the wish of the body of shareholders to listen to this gentleman, I have no objection to listen to him. I put it to you whether you desire to listen to this gentleman or not.

Mr. CLARKSON: Then I say I will be heard. I have been a shareholder for 17 years.

The CHAIRMAN: Those in favour of this gentleman addressing the meeting hold up their hands.

Mr. CLARKSON: Let us have fair play.

Mr. FILER: Will you let me suggest that this gentleman have a hearing? He may have very peculiar notions. All of us have strange notions. I have not the least knowledge of him, but I feel sure that our time will be saved if you listen to him.

Mr. CLARKSON: That it will. You are a gentleman.

The CHAIRMAN: There is a desire to take the sense of the meeting as to whether this gentleman is to speak or not. Those who desire that he should speak please hold up their hands (counting); five desire that he should speak. On the contrary (counting); you are not allowed to speak.

Mr. CLARKSON: Are you ashamed of what I am going to say? I shall stay here if necessary for three centuries. As long as one drop of blood flows through my veins I am determined to have my say.

The CHAIRMAN: If you do not keep quiet I shall cause you to be removed from this room.

Mr. CLARKSON: I am going to say what I know about my property. I am determined to have my say. I am determined to stay here if necessary for three centuries.

The CHAIRMAN: We will give you accommodation. Those in favour of the re-election of Mr. George Garden Nicol, please hold up their hands. That is carried.

Mr. NICOL: I beg to return you my thanks for the compliment you have paid me, and I can assure you that my exertions shall be given in the future, as they have been in the past, to promoting the welfare of the Company.

Mr. CLARKSON: As you are re-elected, now help me.

The CHAIRMAN: I now beg to move—

"*That John Denison Pender, Esq., who now retires, be and is hereby re-elected a Director of the Company.*"

The VICE-CHAIRMAN: I second that.

The CHAIRMAN put the motion, and it was carried.

Dr. WALLER: I have the honour to move a resolution which has been placed in my hands with reference to the election of the outgoing auditors. I am sure there will not be a dissentient to that. I propose—

"*That Mr. Henry Dever and Messrs. Welton, Jones, and Company, both of whom now retire, be and they are hereby re-elected auditors of the Company for the current year, at a remuneration of £100 each.*"

Mr. CROCKFORD: I have great pleasure in seconding the motion. I think the evidence of these gentlemen's ability has been in our hands in the wonderful report that has been placed before us. It is as clear and lucid as it can be, and I think it is our bounden duty to re-elect these gentlemen.

The CHAIRMAN put the motion, and declared it carried, adding, that closes the business of this meeting.

Mr. CLARKSON: Now it is my turn. You gave me your word that you would hear me.

The CHAIRMAN: I said I would give you accommodation to stay here.

Mr. CLARKSON: I question the expediency of this everlasting system of laying duplicate and triplicate cables. I have been a shareholder for 17 years, and during the past eight years there has been a cable—— (interruption).

Major LESLIE proposed a vote of thanks to the Chairman.

Dr. WALLER seconded the motion.

The SOLICITOR (Mr. Burt) put it to the meeting, and it was carried.

The CHAIRMAN: I am very much obliged to you.

The proceedings then terminated.

The Direct United States Cable Company (Limited.)

The twenty-fifth ordinary general meeting of this Company was held at Winchester House, Old Broad-street, on the 17th inst., under the presidency of Sir John Pender, K.C.M.G.

The SECRETARY (Mr. T. Finnis) read the notice convening the meeting and the minutes of the last general meeting, which were approved by the present meeting, and signed by the Chairman as correctly entered.

The report of the Directors and statement of accounts were taken as read.

The CHAIRMAN: Gentlemen, I shall as usual go over some of the details of the accounts, and refer a little to what has been going on in our system during the last six months. The revenue for the half-year to December 31st last, after deducting out-payments, amounted to £42,356, and the working and other expenses, including income-tax, but excluding the cost of repairs to cable, were £15,509, leaving a balance of £26,847 as the net profit of the half-year, making, with £2,719, brought forward from the previous half-year, a total of £29,566, which has been appropriated as follows:—Interim dividend of 3s. 6d. a share to 30th September last, £10,624 5s.; interim dividend of 3s. 6d. a share to 31st December, £10,624 5s.; total dividend for the two quarters, £21,248 10s.; balance carried forward to next half-year £8,318—total £29,566. The revenue for the six months at the 1s. tariff shows an increase of £8,168 over that of the corresponding period of 1888, when, however, the tariff was at 6d. for two months and at 1s. for four months. The business of the last four months showed a small increase over that for the corresponding period, when the tariffs were the same. This increase would have been larger but for the interruption to several of the Pool cables in the period compared. I may mention that the Pool traffic at the 1s. rate shows a reduction of something like 20 per cent. as compared with the traffic at 6d. That shows you, gentlemen, that

Digitized by Google

while at the moment when we were working at 6d. there was a very considerable rush of traffic; now that we have settled down, the difference between the 6d. and 1s. rate is about 20 per cent. On the other side of the account a comparison of the expenditure, where it is not practically the same as in the corresponding period of the previous year, shows as follows: In London a reduction of £106 in printing and stationery. On the whole of the London items there is a total saving of £140. At the stations the increases are as follow: £385 in salaries in giving a little promotion to several of our operators, who thoroughly deserve it; £32 in travelling; £32 in medical expenses, and £26 in banking commission. The reductions are as under: £343 in maintenance, £235 in repairs and renewals, and £117 in printing and stationery: for the whole of the stations the reduction is £200. In the remaining expenses there has been a reduction in the law charges of £23, in the duplex royalty of £317, and in insurance of cable £135. On the other hand, the income tax is £82 higher. Excluding the cost of repairs the Company's expenditure during the past half-year is the lowest on record for any corresponding period since the formation of the Company. With regard to the interruptions of the cable, every effort was made, and with complete success, to secure prompt repairs, and the importance of this, particularly during times of competition, cannot be overestimated. It may be mentioned in the present case that, had the repairing steamer been delayed for another three or four days, the repairs effected on the 12th November would in all probability have been prevented for five or six weeks through the bad weather which prevailed, thereby largely increasing the cost of repairs and adversely affecting the Pool revenue. I may mention that that is one of the points in the policy of this Company that we have strictly adhered to, and in carrying it out we have never yet had any reason to regret—that is, when the cable is broken the sooner we can get a ship sent to repair it the better. We have sent out our ships in all weathers. We have been told it was no use sending a ship in this and that weather; but, gentlemen, the weather here is very different from what it may be where we want to go to. At all events, taking our policy as a whole, it has been successful. Had that policy been strictly practised all round, there would have been, I believe myself honestly, £20,000 more in the pool to divide to-day than there is, on account of the delay in repairing the cables. That is a very large sum, £20,000, in the half-year, and I am quite certain that the example your small company has set will be noticed, and probably noticed for good in the conduct of submarine business generally in the future. The reserve fund account, after being credited with £4,098, the interest on investment, and debited with £4,119, the cost of repairs, now stands at £242,027. No addition to the fund has been made this half-year out of revenue, but this is only the interim half-year, and it must not be overlooked that the Company's cable has, in the course of the last two years, been renewed in parts to the extent of about £35,000. At the last half-yearly meeting, in referring to the reserve fund, I stated that that fund would have to be looked to at no very distant date. I am not going to make any proposal to you to-day with respect to the reserve fund, but six months hence, at the termination of our financial year, I shall make a proposal which I think will strengthen the Company, and will not materially change the dividend. We must try and find out some way of keeping up our income. At the same time, we must find some way of building up the reserve fund, which we have drawn upon pretty frequently. During the time of the competition we were anxious to keep our shareholders as happy as possible, seeing that there was a reduction in our dividend, and £25,000 was applied out of reserve fund towards the payment of dividends, and now that we are working at a higher rate we must try and put our reserve fund in as good a position as it stood at in previous years. At the same time, I am bound to say that while we have drawn from the reserve fund and have put the money into the cable, it has improved the value of our property, so that by adding a certain amount of good cable from time to time to our present cable we should find at the end of a certain number of years that we had replaced it out of reserve fund, and made that fund a strong arm of strength to us in the event of another cable being required. These are details which I think we are justified in putting before you as fully as we possibly can. I always think that the more confidence the shareholders have in the directors the better the machine works altogether. I may now tell you that the company's investments, standing in the balance-sheet at £239,180, are now worth about £264,000, or nearly £25,000 more than they cost the Company. Therefore, you see your securities are not being badly managed after all. I have now given you all the information probably that I originally intended to give you in connection with the working of the Company, but I think it may interest you just to take a short review of this Company, because I think I can show you that after all, at the present moment, with the present dividend, we are in not at all an unsatisfactory position. The dividend paid when only six or eight cables were in the Atlantic was 5 per cent. We accumulated then a considerable amount of reserve, and, as I told you, that reserve has proved very useful to us. The dividend now paid is 3½ per cent., but there are now ten cables to share in the traffic. Therefore, you see, we have in the Atlantic now ten cables against six, and we are paying 3½ per cent. against 5 per cent. It is a very curious fact that when our tariff was 2s., and when we had six to eight cables in the Atlantic, our earnings never quite reached a million sterling. I believe we got to £950,000, but never to a million, which it was our ambition to get to. Something, however, occurred, and the result was that we never reached that point. We are now working at 1s., and we have altogether got to very close upon £800,000, but that £800,000 has to be divided among ten instead of, as before, six cables. That makes a great difference. I want to show you this, that it is very remarkable how little the revenue from Atlantic traffic has progressed during these years—that is to say, the money that has been got out of the Atlantic by the cables has varied from between £500,000 and £950,000, and now with a sort of medium price we are standing with a gross income by all the companies of about £800,000. I should like very much to see the million back again if it is possible to do it. I believe it is possible to do it, but I do not see my way at all to change the 1s. tariff. There is, however, a sort of system prevailing abroad now that property must be a little more taxed, and that the labouring man must go with a less burden on his shoulders, and I think we must go with the fashionable idea, and see if we cannot get a little more out of the moneyed people, and leave the other class of our customers to enjoy a low and satisfactory rate. We must do something, and exercise our ingenuity to try and get up our traffic a little. But with all that I am bound to say to you that the position of the Company now, as compared with what it was when the present Board became the executive, is a satisfactory one. At that time we had 483 shareholders, but we have now got 1,306—of this number only about 8 per cent. are old shareholders, the remaining 92 per cent. being members who have come in since 1887. When we began to agitate, the shares of this Company in the market were about £7. They rose upon our agitation to £12. They even went higher than £12. When we took the Company in hand there was a very heavy debt of £100,000, which we in a very short period cleared off. More than that, our shares are £20 shares. They stand in the market to-day at about £10, but you are getting 3½ per cent. on £20—in other words, those who came later into the concern along with us are practically getting their 6½ per cent. to 7½ per cent. for their money, which is not a bad investment in these times. It is a very difficult thing for a man who is desirous of investing his money to get more than from 3 to 4 per cent. for it. Therefore, I say, taking things all round, we are not in a very unsatisfactory position. As I said, I have referred to two or three points which I thought would be interesting to you, and I will now conclude by saying this, that our cable was never in a better working condition than it is at the present time. When breaks occur we are apt to lose custom, but there has been a steady increase in our customers during the last three months. If

I take our capital, our earnings, and our reserve fund, I think I may say, without any hesitation, that there is no Telegraph Company existing at the present time that occupies a sounder and better position than the Direct United States Company. With these remarks, I beg to move—

"That the report of the Directors, dated January 8, 1890, together with the statement of accounts to December 31, 1889, annexed thereto, be, and the same are, hereby received and adopted."

Mr. WILLIAM FORD: I beg to second that.

The CHAIRMAN: I shall be glad to answer any question that any shareholder wishes to ask before I put the resolution. No one rising to address the meeting, he put the motion, and declared it carried unanimously. Continuing, he said: I think that concludes the business of the meeting, and if I am spared to meet you here six months hence, when we come to the end of our financial year—when we shall talk more about our finances than we have done to day—I hope we shall have as pleasant a meeting and as happy a termination to it as we have had to-day.

Mr. HANCOCK proposed a cordial vote of thanks to the Chairman, Directors, and staff. He expressed disappointment at not seeing the traffic increased as he had expected, in view particularly of their being so many Americans in Europe. The position of the Company he regarded as very much superior to what it was some time ago, and altogether he thought the position, if not quite satisfactory, was full of promise for the future. He thought that the publication of the returns of the traffic might now be resumed.

Mr. VARLEY, in seconding the motion, expressed his satisfaction at the intimation of the Chairman with regard to increasing the reserve fund.

Mr. HUMPHREYS said a few years ago the American cable companies used to publish their returns, but he was opposed to it very much, and at length the system ceased, and with it all its attendant evils. He trusted for his own part that the system would not be renewed.

The CHAIRMAN, in reply, attributed the fact that the traffic had not increased so much as some of them had anticipated to the coding system adopted, especially by merchants. He was astounded at the vast amount of information which could be expressed in two words only by means of those coding systems, which could not be stopped. In fact, it was the growth of this system of coding which prevented their own growth. Submarine cable companies must rely for their progress in the future upon the necessity which their systems had now become to merchants and to every class of the community. With reference to the reserve fund, that was the strength of any company. In their own concern they had not aspired so much to high dividends, and for that reason they had always preferred to strengthen the reserve fund rather than pay, as they occasionally might have done, ½ per cent. extra to the shareholders. They could not publish the returns of the traffic alone owing to their agreements with other companies, and he did not think it would be advisable to do so under the circumstances. He thought, too, that by the publication of the returns artificial speculation on their property might be created, and that would be prejudicial to the interests of the shareholders. Every half-year, however, in the report and accounts which they furnished, they gave the shareholders very full information, enough, he thought, to afford them ample food for digestion during the following half-year. On the part of the Directors, he was much obliged to them for their vote of thanks. The Board appreciated the confidence of the shareholders highly, and trusted that they would always enjoy it.

The proceedings then terminated.

NEW COMPANIES REGISTERED.

THE PURNELL HIGH-SPEED GAS ENGINE AND MANUFACTURING COMPANY (LIMITED).—Registered by Paddison, Son, and Fullilove, 14, Gray's Inn-square, W.C., with a capital of £50,000 in £1 shares. Object: To carry into effect an agreement made January 2nd between J. J. Purnell and J. White on behalf of the Company, and to acquire the patents, inventions, and improvements, machinery, business, and contracts referred to in the said agreement.

THE ELECTRICAL ENGINEERING CORPORATION (LIMITED).—Registered by Dowson, Ainslie, and Martineau, 28, Bedford-row, W.C., with a capital of £150,000 in £5 shares. Object: To carry into effect two agreements, dated January 9th, and made between R. B. Rennie (on behalf of the United Electrical Engineering Company) and John G. Statter (on behalf of the Company), and John G. Statter (on behalf of J. G. Statter and Co., Limited) and E. Manville (on behalf of this Company), being agreements for the transfer to this Company of the respective businesses of the United Electrical Engineering Company (Limited) and J. G. Statter and Co. (Limited). The first subscribers are:—

C. Sannel, 175, Sutherland-avenue, W.
W. L. Madgen, 3, Princes-mansions.
W. G. Ainslie, M.P., 21, Ennismore-gardens.
J. G. Statter, C.E., Alliance Engineering Works, West Drayton.
H. B. Statter, Old Hall, Snapethorpe, near Wakefield.
P. E. Scrutton, Alliance Engineering Works, West Drayton.
E. Manville, 3, Princes-mansions, S.W.

There shall not be less than three nor more than nine directors. The first are W. Statter, H. B. Statter, J. G. Statter, C.E. Charlesworth, C. Sannel, W. G. Ainslie, E. Manville, and W. L. Madgen, of whom J. G. Statter, E. Manville, and W. L. Madgen shall be managing directors. Qualification £500. Remuneration, £250, and one-tenth of profits after 10 per cent. dividend.

CITY NOTES, &c.

ANGLO-AMERICAN TELEGRAPH COMPANY (LIMITED).—At a meeting of the Board of Directors of this Company, held on Friday last, it was resolved to recommend to the proprietors at the next half-yearly genera meeting of the Company, to be held on the 31st inst., the declaration of the following dividends:—1. A balance dividend of 15s. per cent. upon the ordinary Consolidated Stock for the year ended December 31, 1889. 2. A balance dividend of £1. 10s. per cent. upon the Preferred Stock for the year ended December 31, 1889, both payable on February 1st next, less income-tax, to the stockholders registered on the books of the Company on the 13th inst. After paying the foregoing dividends there will be an estimated balance of £2,247 to be carried forward to the next account. The above dividends, together with those already paid will amount to £2. 15s. per cent. on the ordinary Consolidated Stock, and £5. 10s. per cent. on the Preferred Stock for the year 1889. The register of transfers will be closed from the 17th to the 31st inst., both days inclusive. The ordinary general half yearly meeting will be held at Winchester House, Old Broad-street, E.C., on Friday next, January 31st, at 2 o'clock.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended January 17th amounted to £4,759.

CUBA SUBMARINE TELEGRAPH COMPANY.—This Company, after providing for the dividend on the Preference shares, and placing £1,000 to the reserve fund, recommend a dividend on the ordinary shares at the rate of 9 per cent. per annum, tax free, leaving £404 to be carried forward.

EASTERN TELEGRAPH COMPANY.—This Company announces the opening for traffic of a new cable between Zanzibar and Mombassa on the East Coast of Africa. The rate for telegrams to Mombassa will be the same as to Zanzibar.

EASTERN AND SOUTH AFRICAN TELEGRAPH COMPANY.—This Company announce the payment by interest warrant, on February 1st next, of interest for the half-year ended January 31st on their Four per Cent. Mortgage Debentures.

WESTERN COUNTIES AND SOUTH WALES TELEPHONE COMPANY (LIMITED).—Warrants for the interest on the Preference shares of this Company to December 31st last, payable at the National Provincial Bank, Bristol, on the 21st inst., were posted on Monday last.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended January 17th, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited), were £3,432.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The receipts of this Company for the half-month ended January 15th show an increase of £476 as compared with the corresponding period.

WOODHOUSE AND RAWSON UNITED (LIMITED).—The Directors of this Company have decided to pay an interim dividend for the half-year ended the 31st December last, in respect of profits realised since the formation of the Company, at the rate of 8 per cent. per annum on the Preference shares and of 15 per cent. per annum on the Ordinary shares of the Company, payable on the instalments from the date of their payment.

THE NON-CONDUCTOR OF ELECTRICITY.

VULCANISED FIBRE,

PATENTED.

This new material is supplied in two qualities, Flexible and Hard.

The FLEXIBLE is a substitute for Leather, Rubber, Gutta Percha, &c., and is extensively used by Brass Founders, Axle Makers, Hydraulic, Sanitary, and other Engineers, Pump Makers, Carriage Builders, &c.

It makes the best Hot and Cold Water Packings, and for Axle Washers of all kinds it is unequalled.

The HARD is a substitute for Metals, Hard Wood, Ivory, Vulcanite, Ebonite, &c., and is a good Insulator.

Sold in sheets, 5ft. 6in. by 3ft. 6in., varying in thickness from 1-50in. to 1in.

FLEXIBLE, 2/- per lb.; HARD, 2/3 per lb.

MOSSES & MITCHELL, 70 Chiswell-st., London, E.C.

JABLOCHKOFF'S
DISTRIBUTION PATENT

(Being a Patent for "Producing and Dividing Electric Light," No. 1996 of 1877.)

THE UNITED ELECTRICAL ENGINEERING COMPANY (LIMITED)

Are Proprietors of the above Patent, and Warn the Public against Infringement.

The following are Licensees:—

Anglo-American Brush Electric Light Corporation, Limited.
Crompton & Co., Limited.
S. Z. de Ferranti.—London Electric Supply Corporation, Limited.
W. T. Goolden & Co.
Hammond & Co.
Wilson Hartnell.
Johnson & Phillips.
Laurence, Paris & Scott, Limited.
Nalder Brothers & Co.
Paterson & Cooper.
Ernest Scott & Co.
Siemens Brothers & Co., Limited.
J. G. Statter & Co., Limited.

3, Prince's Mansions, Victoria Street, Westminster.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 611.—Vol. XXIV. FRIDAY, JANUARY 31, 1890. Price Fourpence.

NOTES.

The discussion on the Presidential Address at the Institution of Electrical Engineers yielded several points of interest. Prof. Thompson described an admirably simple piece of apparatus, which he had previously shown at his first Cantor Lecture, for workshop use, for determining the permeability of different specimens of iron. This should prove a useful addition to present testing appliances. Mr. Preece complained of the falling off in the magnetic quality of steel, and his remarks were supported by Mr. Evershed. It was stated that, whereas in 1883 it was possible to get steel having a permanent induction of over 5,000 C.-G.-S. lines, in 1886 the best that could be obtained had only 3,700 lines, and that recent tests show even further deterioration. The important uses of permanent magnets in testing instruments and for other purposes renders this matter worthy of serious attention. We think it doubtful whether this falling off is very general, for Prof. Gray has, we believe, succeeded since 1883 in permanently magnetising steel to an induction of over 7,000 C.-G.-S. lines.

The constantly-recurring subject of electrical terminology was alluded to by several speakers. A word is certainly needed to denote the practical unit of lines of force, which is 10^8 C.-G.-S. lines per square centimetre, although we hardly like the one proposed by Mr. Evershed. The name *Thomson*, like the word *induction*, is suggestive of too many ideas to be confined to one.

The Friday evening lectures at the Royal Institution were appropriately opened last week with an address on "The Scientific work of Joule," by Prof. Dewar, who admirably fulfilled the task which, had he been able to leave Scotland, Joule's fellow-worker, Sir William Thomson, was desirous of undertaking. In the short time at his disposal, Prof. Dewar rapidly reviewed the great field covered by Joule during his 40 years of constant scientific research, illustrating several of his points by striking experiments. The lecture was concluded by the reading of some interesting reminiscences of the great *savant*, which had been kindly furnished to Prof. Dewar by Sir Lyon Playfair. One of them, typical of Joule's enthusiasm for scientific work, will suffice:—"He once suggested to me," wrote Sir Lyon Playfair, "that we might take a trip together to the Falls of Niagara, not to look at its beauties, but to ascertain the difference of temperature of the water at the top and bottom of the fall. Of course the change of motion into heat was a necessary consequence of his views."

The suggestion put forth by Mr. Crompton at the last meeting of the Electrical Trades Committee that an association should be formed for the purpose of collecting, tabulating, and distributing useful electrical data, is without doubt a most excellent one; but, as Major Flood-Page remarked, while we all sympathise with the proposal, it is hardly possible to exaggerate the difficulty of attaining the end in view. Mr. Allen R. Foote, of Cincinnati, who is engaged on a similar task in the United States, reports somewhat ingenuously that "some managers of electric lighting and power stations have intimated to me that there are certain features of their business concerning which they do not desire to answer inquiries: they have acknowledged at the same time, however, that information regarding those very points, if given by *other* companies, would be more valuable to them than any other data that can be obtained." Precisely. We all subscribe to the maxim that the interest of the whole swarm is identical with that of the individual bee, but in such cases as the one in question the individual bee, while ready to drink—to quote the Chairman's words—from "the common fount of knowledge," has a rooted dislike to the necessary preliminary of contributing his particular drop of information to the common fount. However, the experiment is to be tried, and we wish it every success.

The experiments of Sarasin and Rive on multiple resonance in connection with electric oscillation seem to show conclusively that the phenomena discovered by Hertz are much more complex than has hitherto been supposed. It will be seen from the abstract which we publish that the electrical vibrations set up in a Hertz oscillator most probably consist of waves of many periods, just as the sound caused by striking a bell is composed of a multitude of tones differing in pitch. There appears nothing in this discovery which should cause surprise, although the experimental proof of it is most important. We cannot follow M. Cornu in thinking that Hertz's theory is much affected, for although it was assumed that the primary oscillator gave rise to an electric undulation of a single period determinable from its dimensions, yet this assumption is confessedly only made as a first approximation. The very fact that the simple method of calculation of the period of the primary vibrations is debateable, should prepare us to expect more complex undulations. Every analogy with

Digitized by Google

sound and light points, in fact, to the improbability of obtaining vibrations all of one period by any ordinary means. We believe Prof. LODGE has found in his experiments that there is no need for perfect resonance between the oscillator and resonator. This may arise from the same reason that a Helmholtz resonator will respond more or less to any note of about the same pitch as that to which it is tuned, although to the latter it will resonate best; but more probably it is due to the fact that the electric waves set up are of various periods. These experiments of SARASIN and RIVE, however, show the need of caution in deducing the velocity of light from HERTZ's experiments, and also serve to explain the discrepancies between some of the values obtained by HERTZ and the accepted velocity of light.

IT is sometimes good for us to have our fixed opinions directly challenged, and the letter which we publish this week from Prof. SCHUSTER, on the Counter Electromotive Force of the Arc, is a powerful argument against the common belief in the existence of a quantity the measurement of which has been the object of many researches. Our correspondent points out that, in order to obtain this quantity, we have to assume Ohm's law to be true for gases. We have either to assume that the resistance of the arc is independent of the strength of current, or that it increases uniformly with increase of length. These assumptions are no doubt unjustifiable save on experimental grounds. If, however, assuming this, the back E.M.F. is found to be fairly independent of current, there is strong experimental evidence not only for the truth of the assumptions, but also for the existence of the counter E.M.F. Should this not be found constant, we quite agree with Prof. SCHUSTER that the best way of publishing the results is simply as an experimental relationship between the applied E.M.F. and the current flowing.

SOME important tests of the efficiency of Westinghouse transformers, described in detail in the *Electrical World* of January 18th, have lately been made at the Massachusetts Institute of Technology by Mr. W. MARSHALL, under the direction of Prof. C. R. CROSS. The method employed was a calorimetric one, as the use of electrometers was considered unsatisfactory. The loss in the transformer was measured by an ice calorimeter, while a water calorimeter was used to measure the output. Each calorimeter was calibrated by passing a direct current through a German silver coil placed within. The experiments, which appear to have been made with great care, have yielded the result that the efficiency of the Westinghouse transformer lies between 93 and 94 per cent. It is, however, a great pity that tests were only made at full load. The absence of any system of storage with alternating currents makes it very desirable to know the energy absorbed by transformers working with little or no load. In practice, transformers are always joined to the mains, although they may be used for but a few hours a day; and what we need to know is the proportion which the energy given out during the working hours bears to the energy absorbed during the whole day.

As we announced in our last issue, the Brighton Corporation have decided by an overwhelming majority to follow the example of Bradford, and establish a municipal central lighting station on the low-tension system. The five resolutions moved by the Chairman of the Lighting Committee were not, however, passed without a discussion, distinguished alike for its great length and for the unusually thorough grasp of the subject which was shown by most of the speakers. The resolution relating to the price to be charged met with considerable opposition, and not without reason. At Bradford 5d. per unit, if we may judge from Alderman PRIESTMAN's recent remarks, has not as yet been found to pay: that being so, it is difficult to see how the 20 and 25 per cent. profit, which was hinted at by one speaker, is to be made out of 6d. per unit at Brighton, where coal is probably 30 per cent. or 40 per cent. dearer than at Bradford. Estimates of profits rarely err on the side of moderation, and it would be as well even for corporations to start by charging a price allowing a considerable margin for "accidents."

THE opposition of the American telephone companies to the use of the single trolley system of electric traction, to which our New York correspondent alluded in our last issue, has culminated at Cincinnati in a law-suit, which is exciting considerable interest all over the United States. The City and Suburban Telegraph Association, which operates the telephones in Cincinnati, has brought an action against the Mount Auburn Street Railway Company, with a view of compelling the latter to substitute the double for the single trolley system. The telephone company aver that up to the date of the introduction of electric traction their lines worked perfectly, but that since the advent of the single trolley the working of the telephone has been greatly impeded, and at times rendered impossible; and that, being the first in the field, they ought to have protection against this interference. The Street Railway Company, on the other hand, deny that they are responsible for these troubles, and assert that they have as good a right to use an earth return as their opponents. The question in dispute is, it will therefore be seen, one which affords ample scope for ingenious legal arguments. The telephone user (a perennial sufferer from the leakage and induction complaint) would no doubt be glad to see both parties obliged to use complete metallic circuits. Such a consummation is, however, perhaps out of the question; but we cannot help thinking that the disputants might be better employed in arriving at an amicable compromise than in wasting their substance on the gentlemen of the long robe. According to our New York correspondent, this has been done in several instances, the electric traction company agreeing to pay a certain proportion of the expense of changing the telephone service from a grounded to a metallic system.

AT the meeting of the Commissioners of Sewers on Tuesday last the electric lighting of the City was advanced another step by the adoption of the report of the Streets Committee recommending that a contract should be entered into with the Laing, Wharton, and Down Construction Syndicate for the lighting of

Digitized by Google

the Eastern division. Congratulations were exchanged on the advance which was being made.

As will be seen from an extract, which we print in another column, from the half-yearly report of the North Metropolitan Tramway Company, the working of the Barking-road section by the accumulator cars of the Electric Traction Company has given entire satisfaction, and we can but echo the hope of the North Metropolitan directors that Parliament will sanction the introduction of electric traction over that Company's entire system.

Cathedral Lighting.—The cathedral of Notre Dame at Montreal is now lighted by 400 incandescent and 15 arc lamps.

Sevenoaks.—At their last meeting the Local Board resolved to support the Provisional Order of the Electric Trust Company.

Obituary.—We regret to announce the death of Gustave-Adolphe Hirn, the eminent physicist, who died at Colmar on January 14th, in his 75th year.

Coventry.—At the last meeting of the Town Council it was resolved to oppose the Provisional Order promoted by the Midland House-to-House Electricity Company.

Leeds.—At the special meeting of the Leeds County Council held on Tuesday the recommendation of the Joint Committees, referred to in our last issue, was agreed to by 25 votes to 18.

Joule International Memorial.—Subscriptions to the Joule International Memorial Fund should be sent to the Hon. Secretary, International Joule Memorial Committee, Royal Society, W.

Proposed International Exhibition in New York. — *The Times* states that both the New York Assembly and the New York Senate have passed Bills authorising the proposed World's Fair in 1892.

St. Luke's Vestry.—At the last meeting of this Vestry it was decided to offer no opposition to the proposed Provisional Orders of the London Electric Supply Corporation and Brush Electrical Engineering Company.

Edinburgh Exhibition.—At the last meeting of the Executive Committee the question of the applications for space was considered, and it was resolved to recommend that considerable addition should be made to the buildings.

The Electric Light at the Public Record Office.—The electric light, which has recently been introduced in the Public Record Office, is now in working order, the public search rooms and corridors being lighted by 110 incandescent lamps.

Personal.—Mr. J. E. H. Gordon, engineer to the Metropolitan Electric Supply Company, has been appoined consulting engineer to the Westminster Electric Supply Corporation, who are about to erect four central stations in the Westminster district.

Western Union Telegraph Company.—The Western Union Telegraph Company announce that two submarine cables have now been completed between Nova Scotia and New York, establishing direct cable communication from England into their office at 16, Broad-street, New York City.

Hanover.—Owing to the favourable report of Prof. F. W. Kohlrausch, the Town Council of Hanover has voted 1,500,000 marks for the erection of a 15,000-light central station. They have accepted the offer of Messrs. Schuckert and Co., who will use the three-wire system in conjunction with accumulators.

Electric Traction in Germany.—From the *Elektrotechnisches Echo* we learn that the metre gauge line at Hildburghausen-Heldburg will be worked by electricity by Messrs. Hostmann and Co. In the event of this line proving successful, Messrs. Hostmann and Co. will also work the tramway from Weimar to Gera by electricity.

Accident at the Sardinia-street Station.—Early on Wednesday morning the cover of the "blow-off" of one of the boilers at the Sardinia-street Central Lighting Station, which was not properly secured, was blown from its place into the roof of the building. A man employed on the premises was knocked down, and received some injury.

Edinburgh.—Objections have been lodged with the Board of Trade by the Corporation and the Gas Commissioners against the electric lighting applications. The Corporation state that they have never shown a disinclination to use the best available means of public lighting, and have already indicated their intention to apply for electric lighting powers.

Brighton.—Last week's gale severely affected the electric line constructed by Mr. Magnus Volk. Along the Madeira-road about 150 yards of the track has been demolished, owing to the sea washing away the shingle upon which the track is laid. The stopping station opposite the Aquarium was also at one time in great danger of being carried away by the waves.

Telegraphic Breakdown in Lewis.—Great inconvenience, says the *North British Daily Mail*, continues to be felt at Stornoway through the breaking of the telegraph cable, and it is feared that some time may elapse before the fracture is repaired. The cable steamer "Monarch," which had been despatched to repair the cable, was forced, owing to the severity of the weather, to take shelter in Falmouth.

The Action of Lightning upon Gas and Water Pipes.—The *Elektrotechnisches Verein* of Berlin, which is investigating the action of lightning upon gas and water pipes, has issued a request that as many cases as possible of damage so caused, or instances of the effect produced, be described to them. Communications to be addressed to Prof. Dr. von Bezold, im Königlichen Meteorologischen Institut, Berlin W., Schinkelplatz, No. 6.

The Proposed Canadian Cable.—A Bill has been introduced into the Canadian Parliament to charter a Canada Cable Company for a new cable from Ireland to some point on the north shore of the Gulf of St. Lawrence, where connection will be made with the land lines. The Canadian Pacific Railway Company's telegraph lines were completed on Monday last to Halifax, and there is now direct communication by their wires from the Atlantic to the Pacific coast.

Barnsley.—The Barnsley Gas Company have given notice of their intention to terminate the contract for lighting public lamps with gas at the end of June, and the Lighting Committee have recommended the Town Council to invite the electric lighting companies to state on what terms they would establish plant to supply electric light both for public and private purposes within the borough, in accordance with provisions expected to be obtained by Provisional Order.

Bournemouth.—At the last meeting of the Improvement Commissioners it was asked whether any steps had been taken to test the safety of the overhead wires connected with the electric light?—The Clerk said that the Commissioners had represented to the Board of Trade that there were overhead wires in the town, and had asked the Board of Trade to make regulations in respect thereof.—A member of the Committee of Commissioners said that the Committee were unanimous in their opposition to overhead wires.

Beckenham.—At a meeting of the Beckenham Local Board on Monday, the Clerk presented a report upon the proposal of the Electric Construction and Maintenance Company to apply for a Provisional Order, and recommended that the Board inform the Board of Trade that although the consent of the Beckenham Board had not been applied for, they would not withhold consent, provided there was inserted in the Provisional Order a clause giving them the option of purchase of the undertaking at the end of ten years, on terms of 33 per cent. premium.

Dundee.—Another joint meeting of the Town Council and Police Commission in regard to the question of electric lighting was held last week. It was resolved to ask the Gas Commissioners to agree to the reconstruction of their Board on a popular basis, and at their own instance to promote the Provisional Order. The Gas Commission, which met subsequently, unanimously adopted this proposal, and also instructed the clerk to lodge objections against the application for a Provisional

Digitized by Google

Order lodged by the Scottish House-to-House Electricity Company.

Exhibition of Meteorological Instruments.—The Council of the Royal Meteorological Society have arranged to hold, at 25, Great George-street, Westminster, on March 18th to 21st next, an Exhibition of instruments and photographs illustrating the application of photography to meteorology. The Council are anxious to obtain as large a collection as possible of such instruments, and will also be glad to show any new meteorological instruments or apparatus invented, or first constructed, since last March, as well as photographs and drawings possessing meteorological interest.

Bolton.—A special meeting of the Bolton Town Council was held on Saturday last to consider the position of the Corporation in relation to the Provisional Order promoted by the House-to-House Electricity Company. After a long discussion, resolutions were passed unanimously to oppose the measure of the company named, and authorising the Corporation to apply for the requisite powers to supply electricity within the borough. In the discussion it was stated that the putting down of the necessary plant for the supply of electricity would entail an expenditure of from £50,000 to £60,000.

Bristol.—At a meeting last week of the Electrical Committee of the Town Council, the question of introducing the electric light was again under consideration. It was reported that a carefully-prepared estimate for lighting a certain portion of the town had been received from Mr. Preece. It was agreed that the document should be printed, and that another meeting should be held at an early date to take it into consideration. Meanwhile the Committee will advise the Council to oppose the granting of Provisional Orders to the House-to-House Company and the Brush Electrical Engineering Company.

Telephonic Communication in Holland.—In the course of the month the Dutch Bell Telephone Company, says *Industries*, will give a great extension to their system in different provinces by laying special new lines between Amsterdam and Haarlem, Amsterdam and Zaandam, Rotterdam and Dordrecht, &c., in accordance with the Government regulations regarding their construction. After the completion of these supplementary lines, towns not hitherto in telephonic communication will be brought into direct contact, and Dordrecht will be able to converse with Haarlem, and Zaandam with Rotterdam and the Hague. The uniform charge for the use of these telephones is to be 50 Dutch cents, or 10d., for three minutes' talk on the instrument.

Bamberg.—According to the *Elektrotechnische Echo*, the introduction of the electric light at Bamberg has resulted in serious difficulties with the telephone. So long as the lighting current is on, communication with Nürmberg is impossible. Experiments have been made, the results of which tend to show that the disturbances are principally due to earth leakage. All attempts to overcome the noise in the telephone wires have been without success. It is believed by some that the difficulty can be traced to two six-pole machines at the waterworks, as the noise is not discernible when the two, four, and eight-pole machines only are running. The Electric Light Company has therefore agreed to build other dynamos in five weeks; meanwhile the supply of current is suspended.

Australasian Telegraph Statistics.—The miles of telegraph line in Victoria amount to 4,194, representing 10,360 miles of wire, the business of transmission of messages being divided between 595 stations, a greater number than exist in any other Australasian Colony; New Zealand coming next with 473 stations; New South Wales, 460 stations; Queensland, 311; South Australia, 211; Tasmania, 124; Western Australia, 38. In the matter of mileage, New South Wales heads the list with 10,690 miles of line and 22,219 miles of wire; Queensland has 9,166 miles of line and 16,648 miles of wire; South Australia, 5,436 line and 9,775 wire; New Zealand, 4,790 line and 11,617 wire; then Victoria, 4,194 line and 10,360 wire; Western Australia, 2,961 line and 3,234 wire; Tasmania, 1,245 line and 1,848 wire.

The Electric Lighting of the British Museum.—On Tuesday night the trustees of the British Museum invited a large party to a private view of the lighting of the galleries by the electric light. The installation now comprises 137 arc lamps and 827 incandescent lamps. The current is generated by four Siemens dynamos, each capable of giving 450 amperes and 130 volts. The four dynamos are driven in pairs, each pair by a separate engine with a separate counter-shaft. Each engine has a separate steampipe in direct communication with the boilers, and there is an ample reserve of boiler-power. Each of the two sets is capable of working the whole of the lamps in those galleries proposed to be lighted on any one evening. The steam-engines have been supplied by Messrs. Marshall, Sons, and Co., of Gainsborough, and the electrical work has been executed by Messrs. Siemens Brothers and Co. The installation has been carried out under the supervision of Mr. W. H. Preece, F.R.S.

Private Bills in Parliament.—Mr. Campion, the Examiner of Private Bills, has had the following Bills under consideration and found compliance with the Standing Orders of Parliament in each case:—The North Metropolitan Tramways Bill (promoted for the purpose of authorising the use of electricity as a motive power on the system of tramways worked by the company; powers are also sought to raise additional capital not exceeding £100,000 in shares of not less than the nominal value of £10). The Aberdeen Electric Lighting Bill (to authorise the Corporation of Aberdeen to erect and maintain electric lines and works, and to supply electrical energy within the city and burgh of Aberdeen; power is also sought to borrow £50,000, to be secured on the mortgage of the undertaking and of the gas undertaking; in the case of charging consumers for the actual quantity of energy supplied the following is the schedule of charges per quarter: for any quantity up to 100 units £3 10s., and 8d. for each unit over 100).

Electric Traction on the North Metropolitan Company's Lines.—The following is an extract from the half-yearly report of the North Metropolitan Tramway Company, to be submitted to their shareholders on February 5th:—"As mentioned in a previous report, an arrangement was entered into with the Electric Traction Company for working the company's cars on the Barking-road section, and the directors are glad to state that the results during the half-year have been satisfactory. The electric cars have run 34,366 miles, and have carried 469,095 passengers. The cost to this company for electric traction has been 4½d. per mile run (including the wages of drivers), which is less than the average cost per mile run for horse traction over the entire system. The Barking-road section is a short single line with loops, requiring only a low mileage, with a small number of cars, which does not offer such facilities for economic working as a longer line would, with a higher mileage and more cars worked by a larger installation; but the result of the working of electric cars on the Barking-road justifies the directors in hoping that Parliament will sanction the introduction of electric power over the company's system, and enable them to extend its application to other lines."

Alteration in the Conductivity of Various Metals after a Lengthened Exposure to a High Temperature.—The alterations in the conductivity of pure copper, aluminium and magnesium, and of commercial zinc and German silver, after a lengthened exposure to a high temperature, have recently been investigated by J. Bergmann. Discs, 70mm. in diameter, were heated to 300°C., and maintained at that temperature for one hour, and then allowed to slowly cool. The conductivity of the copper was increased by something like 2·4 per cent. by this process, that of aluminium, magnesium, and zinc, being increased respectively by 5, 6·8, and 2·4 per cent. The conductivity of the alloy was, on the other hand, diminished by about ·2 per cent. These results are somewhat similar to those obtained for iron by Mr. Tomlinson, and which were set forth in his Paper on "The Effect of Repeated Heating and Cooling on the Electrical Resistance of Iron," read recently before the Physical Society of London (*The Electrician*, November 29, 1889). Mr. Tomlinson, after successively heating a specimen of iron wire several times to 100°C. and allowing it to cool, found that the specific resistance at 17°C. had diminished from 11,162 to 10,688 C.-G.-S. units, a decrease of about ·25 per cent.

Reading.—At the last meeting of the Town Council an animated discussion took place on a report by Major Cardew, and on a proposal by the Lighting Committee that the Laing, Wharton, and Down Construction Syndicate should be requested to alter the position of their wires, so as to make them cross the streets as nearly as possible at right angles. Major Cardew reported that the work was well and strongly done, but no special attention had been paid to the safety of the public. Several of the wires crossed telephone wires without precautions against contact, suspending wires were not used, and a few of the spans exceeded the regulation length. Mr. Monck opposed the proposal to call upon the Syndicate to rearrange their wires, on the ground that every wire had been put up in its present position by the consent of the Council. If they did not like the agreement with the Syndicate let them say so boldly, and not throw, as they had been doing for the past three months, every possible hindrance in the way of it. The recommendation of the Committee was adopted. At a later stage of the same meeting it was determined to oppose the applications for a licence of the Laing, Wharton, and Down Construction Syndicate, and of the Brush Electrical Engineering Company and the South of England House-to-House Electricity Company for Provisional Orders, on the ground that the Council intends itself next Session to apply for a Provisional Order.

The Cincinnati Inclined Plane Electric Railway.—One of the electric railways which is attracting a great deal of attention among American street railway men is the Cincinnati Inclined Plane Electric Railway, the equipment of which was furnished by the Sprague Company. One terminus of the road is in the centre of the city. The electric cars run to the base of an incline, to the top of which they are carried upon an elevator. Upon leaving the elevator the cars again make connection with the overhead wires, and the line extends to the Zoological Gardens, about six miles out from the city. The dynamos are of the standard Edison type for railway circuits, and they have now been in operation for seven weeks without re-oiling. The self-oiling bearings upon these dynamos are of the now well-known ring pattern, in which the oil is distributed over the interior of the bearings automatically by the revolution of the shaft, and after performing its duty of lubrication is returned to the reservoir, where it has opportunity to cool and settle. The two pints of oil which were placed in the dynamo bearings at the starting of the road have not been added to, and the dynamos have since run without any attention whatever. The grades upon this line are very heavy, reaching in some cases as high as 12½ per cent. The amount of coal consumed per day is about 3½ tons of nut and slack for 17 cars, or an average of one-fifth of a ton per day per car. The steam power required for the operation of these 17 cars is supplied by one 150 horse-power engine.

Launch of the Twin-Screw Cable Steamer "Relay."—On Thursday last week there was successfully launched from the yard of Messrs. R. Thompson and Sons, Southwick, a steel twin screw steamer, designed for submarine cable work, built to the order of J. R. France, Esq., of 11, Queen Victoria-street, and destined for the service on the cables of the Central and South American Telegraph Company, of New York. Her dimensions are—length 240ft., breadth 32ft. 2in., depth of hold to Lloyd's ordinary floors 24ft. She is built on the cellular bottom principle, divided into fore and aft and thwartship divisions, so that she can be readily trimmed when laying cable. There are also three tanks for holding the cable, besides the usual appliances of merchant ships. On the bow and stern are large sheaves for paying out and hauling in the cables. On the main deck there will be fitted a combined picking-up and paying-out machine, by Messrs. Johnson and Phillips, driven by a pair of powerful independent engines. The vessel is fitted with two steam winches, large multitubular donkey boiler, steam steering gear, steam windlass, and steam sounding machine, and all the latest improvements. The boats are fitted with patent disengaging gear and patent sheaves for paying out and taking in cables. The engines have been constructed by Messrs. G. Clark (Limited), Southwick: they are of 180 N.H.P. The vessel being very finely modelled, a high rate of speed will be attained. During their construction the steamer and engines have been under the inspection of Mr. D. Rosser, of Cardiff.

London County Council.—At the meeting of the Council last week the Highways Committee recommended that notice should be given to the Metropolitan and the House-to-House Electric Lighting Companies, to desist from carrying out works which have not received the sanction of the Council, and further that the House-to-House Company be required to remove the iron covers already laid down, and to substitute others of the description specified in the Council's notice of sanction of the company's works. The recommendations were adopted.—At the meeting of the Council on Tuesday the Highways Committee reported that they had considered the 23 Provisional Orders for which application had been made to the Board of Trade and the three Bills to be introduced into Parliament next Session relating to electric lighting schemes. They recommended, amongst other things, that all the Provisional Orders and Bills should be amended so as to make them accord with the legislation in respect of electric lighting; that Provisional Orders and Bills comprising areas for which Parliamentary powers had already been conferred upon more than one company be opposed; that in respect of Provisional Orders and Bills relating to the City, the Council should seek for the same powers as were conferred upon it by the Orders and Act of last year; and that the following Orders and Bills be objected to: St. Martin-in-the-Fields and Strand Electric Supply Order, Strand Electric Lighting Bill, St. Martin-in-the-Fields Electric Lighting Bill, St. Pancras Electric Light Supply Order. The recommendations were agreed to.

Folkestone.—At the meeting of the Town Council on Friday last, the Town Clerk read a report from Mr. Preece on the copy of the proposed Provisional Order and draft contract between Messrs. Crompton and the Corporation, which had been sent to him for the purpose. The following is a brief abstract of this document, which we take from the *Folkestone News* of 25th instant:—"Not being acquainted with the history of the transaction with Messrs. Crompton, I am not aware of the reasons, if any, why the Provisional Order is taken out by Messrs. Crompton. It appears to me that the natural course would have been for the Order to have been taken out by the Corporation, and that the provisions of that Order should have been sublet by agreement to Messrs. Crompton as contractors to the undertakers. Messrs. Crompton and Co. are a limited company of very high standing and unimpeachable reputation, but they are also a firm of manufacturers with a limited capital, quite insufficient to carry on their own business and enter into many contracts such as that proposed to be entered into with the Corporation of Folkestone without enlarged financial powers. It is apparently a species of speculation on the part of Messrs. Crompton and Co., which means that the provisions of the Order and of the contract must be ultimately transferred (for a consideration) to some local or other company. The price at which Messrs. Crompton propose to supply public lighting (£24 per lamp per annum) is very fair and reasonable, while that which they propose to charge for private lighting (1s. 4½d per unit) is excessive and absurd." Mr. Preece then criticises the clauses of the draft contract in detail. "Clause 4.—It is proposed to fix the additional lamps at distances not greater than 400 feet apart. The lamps should not be fixed at a greater distance apart than 300 feet. Greater distances will lead to disappointment. Clause 5.—If the Corporation allow the erection of overhead wires—and I know no reason why they should not, for the alarm of danger that has sprung from exaggerated and untruthful accounts of accidents in New York is groundless—then these wires must be erected in accordance with the rules and regulations of the Board of Trade, which expressly exclude *bare* copper wires." In conclusion, Mr. Preece, after suggesting several alternatives, advised the Corporation to oppose the granting of a Provisional Order to Messrs. Crompton, but to apply for a licence, and to complete the agreement with Messrs. Crompton and Co. A resolution was subsequently carried by a large majority, substantially embodying Mr. Preece's recommendations.

MAGNETISM IN IRON AND OTHER METALS.*

BY PROF. J. A. EWING, F.R.S.

IV.

(*Continued from page 260.*)

§ 20. Connection of the Ideas of Permeability and Susceptibility.—We have seen (§ 13) that

$$\mathbf{B} = 4\pi\mathbf{I} + \mathbf{H};$$

and by definition of the susceptibity κ, $\mathbf{I} = \kappa\mathbf{H}$;

$$\text{Hence } \mathbf{B} = 4\pi\kappa\mathbf{H} + \mathbf{H}$$
$$= (4\pi\kappa + 1)\mathbf{H}.$$

But by definition of the permeability μ, $\mathbf{B} = \mu\mathbf{H}$;

$$\text{Hence } \mu = 4\pi\kappa + 1,$$

$$\text{and } \kappa = \frac{\mu - 1}{4\pi}.$$

In a substance such as air, in which the permeability is unity, the magnetic susceptibility is zero. In a paramagnetic substance, in which μ is greater than 1, the susceptibility is positive. In a diamagnetic substance, in which the permeability is less than 1, the susceptibility is negative.

In other words, a paramagnetic substance when subjected to magnetic force acquires a magnetisation **I**, which is in the same direction as the force, and so makes **B** greater than **H**. A diamagnetic, on the other hand, acquires a magnetisation **I**, which is opposite to the force, and so makes **B** less than **H**.

§ 21. A word of caution is, perhaps, desirable here as to the application of the equations which have just been given. It has been assumed that the material to which the magnetic force **H** has been applied, has no magnetism except what the force itself induces. If other forces had acted before, leaving residual magnetisation, the ratio $\frac{\mathbf{B}}{\mathbf{H}}$ would not be a true measure of the permeability, nor would the ratio $\frac{\mathbf{I}}{\mathbf{H}}$ be a true measure of the susceptibility.

Again, it has been assumed that the material is magnetically isotropic—that is to say, that a lump of it is equally capable of taking magnetisation in all directions. If this were not so, if the magnetic properties of the substance were different in different directions (as would, for instance, be the case to some extent in a piece of iron cut from a rolled plate), it would be necessary, if we wished to specify fully the relation of the magnetisation to the magnetic force, to resolve the force into components along axes chosen in the directions which give greatest susceptibility and least susceptibility, find the component magnetisation in each of those directions by multiplying each component force by the value which the susceptibility has in that direction, and then compound these components of magnetisation to find the resultant value of **I**. In such a case the direction of the resultant magnetisation will not in general coincide with that of the resultant magnetic force, and the equation $\mathbf{B} = 4\pi\mathbf{I} + \mathbf{H}$ will be true only when interpreted in its vector sense.

But in the cases of magnetisation in iron which have ordinarily to be dealt with, it is not necessary to take account of this consideration, for the material is either sufficiently nearly isotropic, or the direction of the applied magnetic force coincides with an axis of greatest or least magnetic susceptibility, and the effect is that **I** and **B** have the same direction as **H**.

§ 22. Influence of the Form of Bodies on the Magnetisation induced in them.—When a body is placed in a magnetic field the degree to which it becomes magnetised depends not only on the original strength of the field and on the permeability of the substance, it depends also (often in very great measure) on the form of the body. This is because the body, in becoming magnetised, generally disturbs the field, causing the magnetic force at any point within or near the body to be different from the force that existed there before the body was introduced. The free magnetism which is developed by the body's magnetisation contributes to produce magnetic force, and so affects the resultant value of the force at any point, inside the body or outside, that is not too far off to be sensibly affected. With iron and other very susceptible materials this disturbance of the field is often so great that the original value of the magnetic force is not even a rough approximation to the value the force assumes when modified by the magnetisation of the body. The intensity of magnetisation at any point within the body depends on the actual value which the magnetic force assumes at that point, and this in its turn depends partly upon the magnetisation of the body as a whole. When we wish to examine the magnetic susceptibility or permeability of a substance, we require to know the actual value of the magnetic force within it, for the purpose of comparing that with the intensity of magnetisation, or with the magnetic induction there. The permeability is measured by the proportion which the induction **B** bears to the strength which the magnetic force **H** actually has at the same place, not to the strength which it may have had there before the body was introduced, nor to the strength which it may still have in external parts of the field.

We have, therefore, to take account of what may be called the reaction of the magnetised body upon the magnetising field.

In very many cases the reaction of the body upon the field is too complex to allow a mathematical examination of it to be practicable. With bodies of irregular form it is out of the question to calculate beforehand what will be the magnetic force and the magnetic induction at internal points, having given the original strength of the external field and the permeability of the substance. The problem is determinate, but too difficult to attack. Even so apparently simple a case as that of a short cylindrical iron rod with flat ends, placed lengthwise in an originally uniform field, presents difficulties so formidable that no exact solution has been given. The difficulty in the case of such a rod is aggravated by the fact that even though the rod be perfectly homogeneous to begin with, the susceptibility or the permeability is not uniform throughout when the rod becomes magnetised. This is because the magnetisation is not uniform, and, as we shall see later, the permeability of iron depends to a considerable extent on the intensity of magnetisation. The reaction of the rod upon the original field tends to reduce the magnetic force at internal points, but this effect is unequal at different parts of the length. It is least at the middle of the length; hence the magnetic force, and consequently the induction also, is greatest there and is less near the ends.

§ 23. Long Rod placed Lengthwise in a Uniform Field.—When the rod is long in comparison with its breadth and thickness the effect of its free magnetism in reducing the magnetic force is less than when the rod is short, especially in the middle region of the length, because the ends, in which the free magnetism chiefly resides, are too far off to have much influence. The amount of magnetic induction is consequently greater in a long rod than in a short one of the same breadth and thickness, the original strength of the field and the permeability of the substance being the same in both cases. When a very long rod is placed lengthwise in a uniform field the influence of the ends becomes almost insensible, and the actual magnetic force at points within the rod is then almost the same as at points outside, except near the ends. The magnetisation will be practically uniform throughout the middle region, but will fall off towards the ends.

When the substance of the rod is very permeable, the rod must be very long relatively to its transverse dimensions before we may neglect its reaction upon the magnetic field, and before we may treat the magnetic force at internal points near the middle as sensibly equal to the force at external points, and the magnetisation as nearly uniform. When the substance is less permeable a shorter length will give an equally good approach to uniform force and uniform magnetisation.

§ 24. Analogy of Induced Magnetisation to Electric Conduction.—The concentration of magnetic induction which takes place when a permeable body is placed in a magnetic field is analogous to the concentration of electric flow which may be

* All rights are reserved.

brought about by immersing a piece of copper in a tube full of mercury, through which an electric current is passing. Let the tube be wide and long, and let the current in it be uniformly distributed over the whole cross-section: we have in this the analogue of a uniform magnetic field. Suppose a short piece of copper wire to be inserted and held lengthwise anywhere near the axis of tube. The lines of electric flow, which before were straight and parallel, converge more or less towards the piece of copper, preferring to crowd into it, because its conductivity is much greater than that of the surrounding medium. The whole current is divided between the copper and the mercury around it, the copper taking a share that is greater than the proportion which its cross-section bears to that of the whole conducting tube. The current enters and leaves the copper not at the ends merely, but also along the sides, especially near the ends. If the piece of copper is short, there can be no more than a slight convergence of the flow into it. For instance, to take an extreme case, a little disc of thin copper plate placed in the mercury, so that it faces in the direction of the flow, has little more conduction through it than through an equal area of the surrounding liquid. In other words, the disc produces but a slight disturbance of the distribution of flow in the tube. On the other hand, a long thin copper wire set lengthwise will gather much of the flow into itself, and if the wire be very long its share of the whole will be greater than the amount taken by an equal section of the mercury in the proportion in which the conductivity of copper is greater than that of mercury. Substitute magnetic permeability for electric conductivity, and magnetic induction for electric flow, and we have a nearly perfect analogue of what happens when an iron rod or wire is placed in a magnetic field.

There is, however, this important difference, which makes the magnetic case less simple than the other. The electric conductivity of the copper is a constant quantity, independent of the strength of current in the metal; whereas the permeability of iron depends on the actual intensity of magnetisation, and consequently varies (in general) to some extent throughout the piece.

§ 25. **Cases in which the Magnetisation is Uniform: Ellipsoid.**—In certain special cases it happens that when a magnetisable body is placed in a uniform magnetic field, the magnetic force at all points inside the body is uniform, though its value there is not the same as at external points. A very important instance in which this is true occurs when the form of the body is that of an ellipsoid, the material being homogeneous, so that the permeability has the same value throughout. In such a case it may be shown that the effect of an originally uniform external field is to produce a strictly uniform magnetisation.*

Let the ellipsoidal body be made of a paramagnetic material, such as iron, and let it be placed in a uniform field: then the originally straight and parallel lines of the field become bent, so that they converge on it, as the lines converge on the sphere in Fig 5. The reaction of the body on the field is such that the magnetic force at outside points near the body is no longer uniform. But at internal points the effect of the reaction is different. The force becomes uniform there, with a value, however, which is less than the value it had in the undisturbed field. This uniform internal force implies uniform induction and uniform intensity of magnetisation—that is to say, each of the quantities **H** and **I** and **B** is uniform throughout the whole of the body; but it must be borne in mind that **H** differs, and often differs greatly, from the value which the force had originally, and still has in distant parts of the field. The amount of this difference will depend on the shortness of the ellipsoid and the intensity of its magnetisation. For brevity we shall use **H′** to designate what may be called the external force—that is, the original value which the force had before the field was disturbed, or, what is the same thing, the value which the force still has at distant external points; and we shall keep **H** to mean, as usual, the actual magnetic force at points within the metal.

§ 26. **Magnetisation of an Ellipsoid** (*continued*).—The case of an ellipsoid subjected to the action of an originally uniform field is of so much practical interest that it is worth while to state here some of the results of calculation which are applicable to it.

Suppose the ellipsoid to be set with one of its axes pointing in the direction of the magnetic force. Let c be half the length of this axis, and a and b half the lengths of the other axes, which point in directions that are perpendicular to the direction of the force. It will suffice to take the case of an ellipsoid of revolution, in which $a = b$.

The original external force being **H′** and the force actually operative being **H**, we have

$$\mathbf{H} = \mathbf{H}' - \mathbf{N}\,\mathbf{I},$$

where **N** is a number depending on the relation of the length of the ellipsoid to its transverse dimensions. We may express **N** in terms of the eccentricity e. When the ellipsoid

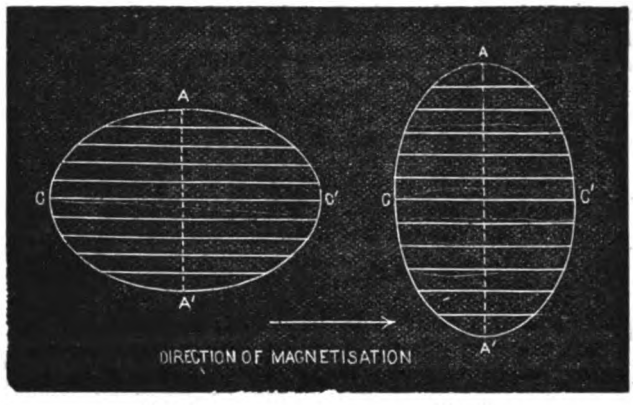

Fig. 7. Fig. 8.

is of the prolate or elongated form, Fig. 7 (the polar diameter $2c$ or CC' greater than the equatorial diameter $2a$ or AA'), $e = \sqrt{1 - \frac{a^2}{c^2}}$, and

$$\mathbf{N} = 4\pi\left(\frac{1}{e^2} - 1\right)\left(\frac{1}{2e}\log_e \frac{1+e}{1-e} - 1\right) \quad . \quad . \quad (1)$$

When the ellipsoid is much elongated this expression approximates to the following simpler form:—

$$\mathbf{N} = 4\pi\frac{a^2}{c^2}\left(\log_e \frac{2c}{a} - 1\right) \quad . \quad . \quad . \quad . \quad (2)$$

When the ellipsoid is of the oblate or flattened form, Fig. 8 (the polar diameter $2c$ less than the equatorial diameter $2a$), the eccentricity e is $\sqrt{1 - \frac{c^2}{a^2}}$, and

$$\mathbf{N} = 4\pi\left(\frac{1}{e^2} - \frac{\sqrt{1-e^2}}{e^3}\sin^{-1}e\right) \quad . \quad . \quad . \quad (3)$$

(To be continued.)

UNDERGROUND MAINS.

BY G. L. ADDENBROOKE.

III.

(*Continued from page 287.*)

Having in the first two articles touched briefly on earlier experiences on the forms of conduits used in telegraphic work, and the lasting qualities of some of the principal material employed, it is proposed now to pass on to systems at present in use for electric lighting.

The Edison Company's System.

This, the oldest of the complete systems of underground mains worked out commercially in all its details, is now usually laid down in the following manner:—

The system naturally divides itself into three parts—the feeders, the mains, and the branches. All these are made on the

Digitized by Google

principle of placing—for the three-wire system—three copper rods lapped round with yarn in wrought-iron tubes; the yarn keeps the rods at the proper distance apart, and the tube is entirely filled with a bituminous insulating compound, beyond which the conductors project a few inches at each end. These tubes are made in lengths of 20ft. 6in. For the feeders the neutral wire is about half the size of the positive and negative conductors; for the mains all three conductors are usually of the same size; the feeders, besides the three rods, have pilot wires inserted in them, one for each conductor. These lengths of tubing are laid in the roadway about two feet deep, and are usually protected from injury by a stout plank laid above them. The conductors in each length of tubing are joined to those in the next length by short pieces of flexible stranded cable, having solid metal sleeves sweated on each end, as shown in the sketch (Fig. 1). These couplings are arranged to bear everywhere the full section of the rods they connect; the hollow portion of the connecting piece or sleeve is slipped over the copper rod, which it fits, and is then very carefully soldered to it. The same form of coupling is used throughout.

Fig. 1.—Flexible Copper Connecting Piece employed by the Edison Company.

To join one section of the piping to the next, and for taking off branches, junction boxes are used. The sketch (Fig. 2) gives a general idea of one in which a branch is taken off. For the three connections the boxes are made in a similar way, but without the arrangement for taking off the branch. A short distance from the end of each pipe, coming into the box, two iron castings which fit the pipe are clamped together. The two portions of these castings which are nearest the box are hemispherical in shape outside, and form together one portion of a ball-and-socket-joint; the junction box has hemispherical hollows at each place where the pipes enter it, which fit closely over the balls, so that a ball-and-socket-joint is formed with a limited range, allowing the tubes to be set at more or less of an angle with each other. When the couplings have been made in a box the top half is

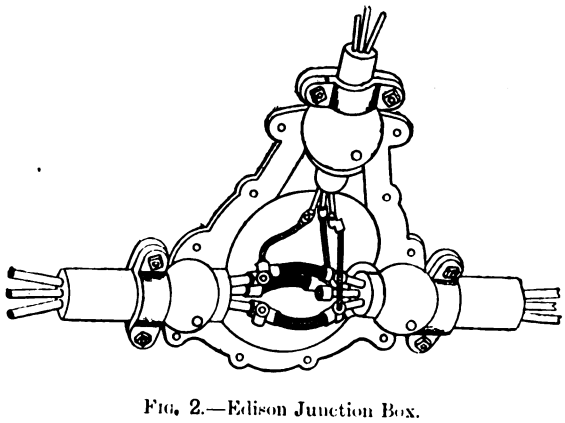

Fig. 2.—Edison Junction Box.

screwed on, and the whole is run full of a hot insulating compound, which solidifies on getting cool. Elbow boxes are used for getting round corners. The tubes are made of different sizes to hold copper conductors varying in diameter from $\frac{3}{4}$in. to $\frac{1}{4}$in., and the junction boxes are also made so that a through box can be replaced by a box for taking off a branch at any joint. Manholes are provided at different places over the system into which the tubes are brought, and where cut-outs are placed and different portions of the network of conductors joined together, it being as far as possible usual to connect each portion of the mains so that they will be supplied from more than one feeder.

For feeders in large stations, where the section of copper required is very great, the Edison Company do not confine themselves to the use of this form of construction, but frequently lay down a number of iron tubes in concrete and parallel to each other, into each of which pipes an insulated cable is drawn. This method admits of more copper being got into the same space than the former one, as the junction boxes take up a good deal of room, and prevent the tubes holding the conductor from lying very close to each other.

This system may at first sight look rather cumbrous and expensive, but it is made of cheap material, while the work itself is of a sound and substantial character, likely, if well laid down, to last indefinitely. As it has been very largely used in America by the Edison Company now for several years, they have been able to perfect the details and eliminate weak points from actual experience.

Other American Systems.

In several of the leading towns something has been done towards getting a portion of the telephone wires put under ground, for which bitumen or wood conduits have been largely used, the cables being lead covered. As far as electric light mains are concerned, at the last year's meeting of the American National Electric Light Association a committee reported that they had sent circulars to all the local companies on this subject. Out of 130 answers only seven of the companies sending them appear to have had experience of underground wires, and none of these are enthusiastic on the subject. It must be pointed out that this related to high-tension current work for arc lighting, the average tension being 1,893 volts, and the current 10 amperes. For alternating-current house-to-house distribution but little underground work has been used in America so far. Where conduits are made use of, there is usually an overhead network in connection with them for local services. In Chicago a good deal of work has been done in the sewers, okonite lead-covered cable being successfully used: this is supplemented by a system of iron pipes and man-holes much like that in New York. In the eastern cities several systems have been more or less tentatively tried, but the general consensus of opinion appears to be in favour of the method of construction adopted, after many trials, by the Board of Electrical Control in New York, and which is as follows:—

The Iron Pipe and Man-Hole System.

Cast-iron socket-pipes three or four inches in diameter are laid between large man-holes. In places where there are many

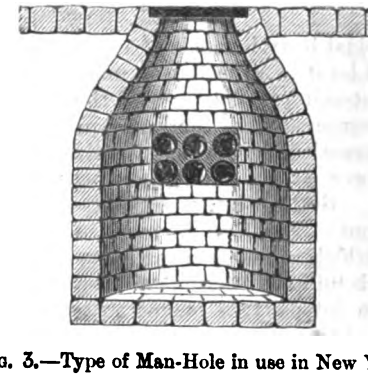

Fig. 3.—Type of Man-Hole in use in New York

cables, several lines of piping are laid parallel to each other, concrete being employed to keep the lines straight and in their places. These lines of piping, as well as the man-holes, are usually placed in the roadway. The man-holes are placed at varying distances apart, according as the district is a busy one or not. They are much deeper, larger, and more important than those generally used in European work, it being intended to radiate the cables for local services from them, no provision being made for tapping the pipes between. It is, however, probable that some alteration will take place in this respect before long. Fig. 3 shows the general construction of the man-holes. They are about 8ft. deep and 4ft. across

Digitized by Google

at the bottom. The pipes are shown coming in about half way up. Local connections are taken off nearer the surface. If the man-hole is at the corner of two streets there may be several sets of pipes coming into it in different directions. The man-holes are large enough for a man to stand inside to do jointing work or pulling through; they are closed at the top by a circular iron lid fitting into a suitable casting to receive it. Naturally in places water accumulates in the bottom, and has to be pumped out before the man-hole can be entered; but as there is so large a space inside, and the cables are some distance up, they will usually be out of its reach. Lead-covered cables having 7/16 stranded cores are generally employed, and regular plumber's joints are made on the lead covering when connecting two pieces together.

The Siemens System.

This system, which has been worked out by Messrs. Siemens Bros. and Halske, of Berlin, is one which makes a bold bid to solve the problems both of cheap construction of the cable itself and the cheap placing of mains underground, not only for currents at low tension, but for alternating high-tension currents a'so. For these two purposes cables constructed of the same materials, but differently arranged, are made: for low-tensions the cables are of the ordinary character; for high-tensions the cables are concentric, one set of wires being outside of and surrounding the other.

The way these cables are made is as follows:—Round the copper core a thick layer of jute is laid, which forms a sort of foundation for the insulating material. This material consists

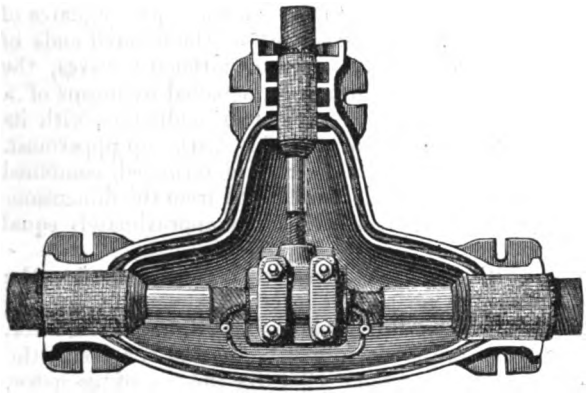

Fig. 4.—Siemens Single Cable Junction Box.

of a special bitumenous compound rendered somewhat flexible by the addition of heavy oils, and with it the jute covering is thoroughly saturated and filled, so that the whole forms a solid mass. As these materials are cheap a very thick insulating covering can be used on a cable without incurring great expense. In the ordinary cables a lead tube is drawn over the insulating material, and this tube is then covered with a strong and well-compounded tape. Next a couple of spiral lappings of iron strip are put on in opposite directions, and finally the whole is covered with layer of heavily-compounded jute yarn.

For the concentric cables for high-tension currents the construction is on very similar lines. Round the centre copper core comes insulation, only thicker than for the low-tension cables. Then we have the outer copper conductors laid evenly round this insulation. Next comes another layer of insulation, followed by the lead tube, the outer coverings of the cable being the same as already described.

Cables constructed in this manner are made not only for feeders and mains, but for branches and connections to customers, so that the system is quite complete. The cables are intended to be laid directly in the ground without further preparation or protection, it being considered that they are strong enough to withstand the effects of any ordinary ill-usage they are likely to be subjected to, and that the protective coverings will be sufficient to preserve the insulation sound and intact.

A special set of junction boxes have been worked out to suit these cables, both ordinary and concentric, as well for joining them end to end as for local connections for customers, and for service mains. The nature and construction of these boxes will best be seen from the figures. Fig. 4 shows a junction box for the single cable, with a third aperture for taking off a connection. The through junction box is exactly similiar, only without this additional aperture, so that it is oval in form, as in Fig. 5. Fig. 5 shows a through junction box for a concentric cable. It will be observed that the outer conductors are spread out in a circle and clamped between two metal surfaces, the bolts which tighten the clamps also serving for the through connection. The box for taking off connections is of the same shape as Fig. 4. It will be seen that these boxes are constructed in halves, the edges being grooved out all round and filled with packing. When applied to a cable, the cable is opened and all the outer coverings taken off except the insulation, which projects some way into the box. All junctions are made by means of clamps, and no solder is used. When a connection is completed the top of the junction box is put in its place, and the two halves are held together by strong clamps. In each junction box there is a hole closed by a screw plug. After a box is clamped together it is filled with a heavy mineral oil through this hole, which improves the insulation and keeps it constant. These junction boxes, as a rule, lie buried in the ground in the lines of the cable, which is usually laid under the footpath.

The Siemens system has been very largely used in Berlin for low-tension currents, and a description of its working will be found in Prof. George Forbes' Paper on "Foreign Central Stations," read before the Institute of Electrical Engineers in February last (*Electrician*, March 8, April 19 and 26, 1889). Both in Rome and Milan the concentric cables have also now for some time been employed successfully for alternating currents of 2,000 volts, but in Rome the cables have been additionally protected by being laid in wooden troughs filled with cement.

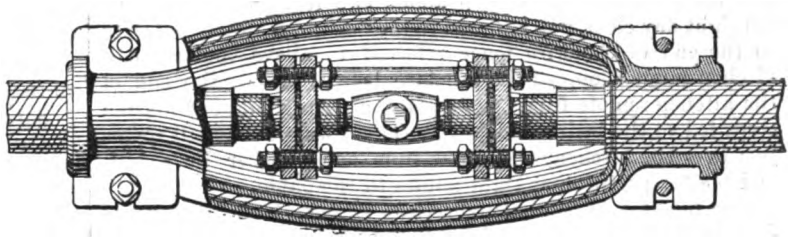

Fig. 5.—Siemens Concentric Cable Junction Box.

Profiting by the experience of their Berlin house, Messrs. Siemens Brothers, of Charlton have lately commenced the manufacture of this class of cables in England, and the concentric pattern is being laid down on an extensive scale by the London Electric Light Corporation (Limited). All their cable is tested for an hour with an alternating current of 5,000 volts before delivery. The cable is about 3in. in diameter over all, and is being laid about 6in. to 10in. deep in the soil under the footpaths. The cables being comparatively cheap in themselves, and easily and cheaply laid, much interest will naturally be felt in the way they work during the next two or three years.

(To be continued.)

Electrical Phenomena at the Santis Observatory.—Remarkable electrical phenomena are witnessed at the new observatory on the steep and isolated Säntis (8,215) in Northern Switzerland. Thunderstorms are extremely frequent; thus, in June and July last year, only three days were without them. As a rule, thunder peals from midday till evening. The noise is short, partly owing to shortness of flashes, and partly to the small amount of echo. The thunderstorms come on quite suddenly in a clear sky. One of the surest indications of their approach is the bristling of the observer's hair. During hail, the iron rods of the house give a hissing sound, asociated with luminous effects.

A SEVERE CASE OF DAMAGE BY LIGHTNING.

BY PROF. ANDREW GRAY, M.A.

Early in the morning of January 7th a thunderstorm of some violence broke over Carnarvon and Anglesey, but passed rapidly away with a few vivid lightning flashes, accompanied by loud peals of thunder. A day or two afterwards I heard it reported that a house in Llandegfan, a small village nearly opposite Bangor, on the Anglesey side of the Menai Strait, had been struck by lightning and almost completely wrecked. I lost no time in visiting the place, and carefully inspecting the house and its surroundings. In view of the recent discussion regarding protection from lightning, I have thought that an account of the situation of this house, the probable course of the discharge, and the damage done, may be interesting to the readers of *The Electrician*.

The house is one of two small adjoining houses which stand near the top of the high ground above the Garth Ferry, on the Menai Strait. These houses stand at right angles to a narrow lane, on either side of which is a bank of earth about three feet high, surmounted by a straggling hedge of hawthorn. Behind the house there runs along the bank, beside the hedge, a fence consisting of upright slabs of slate, placed closely together, and held at the top by a double line of ordinary iron fencing wire twisted round the posts. This wire formed, with the exception of a single gap, a continuous conductor from post to post, from a point a few inches from the back wall of the house and about three feet from the gable end next the lane, to a distance of about 38 yards along the lane, where the bank gave place to a stone wall.

The house struck was the one next the road. It is two low stories in height, and contains on the ground floor a kitchen or living room extending from front to back, and a narrow parlour or bedroom. The kitchen is next the lane, and the flue from it runs up the gable, and terminated before the disaster in a brick chimney at the top about two feet in height. An old eight-day clock was fastened to the back wall, nearly opposite to the end of the wire fence referred to above, and a small kitchen range occupied the fireplace below. From the end of the kitchen remote from the fireplace, a narrow flight of wooden steps led to the bedrooms above. There were two small rooms just over the kitchen, separated from one another by a lath and plaster partition at right angles to the gable.

The inmates of the house retired to rest about 10 p.m. on January 6th, leaving a small fire in the kitchen grate, and awoke at about 1 a.m. to find their house nearly in ruins, and their furniture broken to matchwood. The house had been struck by lightning, which had demolished the chimney at the top of the gable, tearing it away from and destroying a portion of the roof near it, and committing great havoc in the interior, especially in the kitchen and small room below.

On examining the house I found that the line of discharge, or at least one part of it, must have been to the chimney top, thence to a point of the flue just under the ceiling of the kitchen, thence across the corner of the room to the clock, and through the wall to the wire fence, along the wire fence to its end, and across the road there from one bank to the other. Just under the ceiling was a hole from the flue to the interior of the house, and where the clock had stood another hole was pierced to the fence. Each of these holes was wide at the wall face, but within the wall was only about wide enough to admit a walking-stick. That the discharge had passed along the wire fence was plain. At a gap about two feet in width in the wire near the further end, the wet earth had been scattered about so as to thoroughly smear all the twigs of the hedge with mud. The stone wall about four yards further on, at the extremity of the fence, was thrown down, and the bank opposite at the other extremity of the road torn up. Within the house there seemed to have been a violent explosion—the clock, dresser, and drawers were smashed to pieces, the door broken to splinters, the glass broken in the windows, and the stairs leading to the rooms above destroyed. Strange to say, none of the inmates were at all injured—except, perhaps, the wife of the tenant of the house, who says she was awakened by a blow from a falling beam. There was no sign of scorching on any of the articles destroyed.

What I imagine took place is this. A discharge occurred between the cloud and the chimney, and thence along the sooty flue to the point below the ceiling, destroying the chimney and the roof. The further course of the discharge was across the corner of the room and through the wall to the wire of the fence outside, and thence along the wire to earth at the further end. There was nothing to show that any discharge took place through the lower part of the flue and the grate, as the latter was uninjured. The people sleeping above, five or six in number, seem to have been protected by the floor and the beds beneath them from what must have been a violent explosion below. It is remarkable that there was a sufficient discharge at the extremity of the wire fence to throw down the wall and tear up the ground. The wire was connected to earth by a close fence of slate slabs, and besides, was at many places completely buried in the thorn-hedge. The fence and hedge must have been wet, as the night was very stormy, and so there must have been great leakage from the wire. There was no effect of the discharge apparent on the wire.

MULTIPLE RESONANCE IN CONNECTION WITH THE EXPERIMENTS OF HERTZ.*

BY MM. E. SARASIN AND L. DE LA RIVE.

One of Hertz's experiments consists in exciting oscillations in two straight parallel conductors of equal length, each isolated at one end, and connected at the other perpendicularly to a plate of brass placed parallel to one of the capacity plates of the primary oscillator. The reflections at the isolated ends of the secondary conductors give rise to stationary waves, the nodes and internodes of which may be detected by means of a circular resonator placed between the two conductors, with its plane normal to their direction, and the spark gap uppermost. Hertz found that the wave length thus determined, combined with the frequency of oscillation calculated from the dimensions of the primary oscillator, yielded a velocity approximately equal to that of light.

Sarasin and Rive find, however, that they can alter the distance between the nodes and internodes, without altering the primary conductor at all, by employing a different resonator. If the waves given out by the primary are all of one period the wave length should be the same whatever the size of resonator, although the spark distance may be lessened if the resonator is not properly timed to the electric vibrations. The authors have made a great number of experiments with three types of resonators. With each resonator used they have altered the dimensions and arrangement of the primary conductor, the distance apart and length of the secondary wires, and the position of the resonator with reference to them; and in all cases have found that the distance between the nodes is the same for the same resonator, although varying with the resonator used. The annexed table gives the results of their final experiments:—

Distance of Nodes from the free ends of the Secondary Conductors.

	Resonator 35cm.		Resonator 50cm.		Resonator 75cm.	
Distance.	Observed.	Calculated.	Observed.	Calculated.	Observed.	Calculated.
Node.	m.	m.	m.	m.	m.	m.
1st ...	0·60	0·60	0·78	0·78	1·24	1·24
2nd ...	2·03	2·07	2·73	2·67	4·19	4·23
3rd ...	3·56	3·54	4·46	4·56	7·23	7·22
4th ...	5·09	5·01	6·52	6·45		
5th ...	6·45	6·48	8·35	8·34		
6th ..	7·90	7·95				
7th ...	9·42	9·42				

The mean half-wave lengths determined with the three resonators will be seen to be 1·47m., 1·89m., and 2·99m. respectively. The table shows that the distance of the first node from the end of the conductor is smaller than a quarter-wave

* Abstracted from the *Comptes Rendus*, January 13, 1890.

Digitized by Google

length, as is the case with reflection at the ends of open pipes. This distance is very nearly equal to the semi-circumference of the resonator, as the following table shows :—

Resonator.	Distance of First Node.	Semi-circumference.
m.		
0·35	0·60	0·55
0·50	0·78	0·78
0·75	1·24	1·17

This seems to indicate that the reflection in the resonator on the two sides of the spark gap takes place in the same manner as at the ends of the conductor, the two poles of the resonator being internodes always in opposite phase. The authors conclude from the experiments that an ordinary Hertz oscillator gives rise to waves not of one period only but of several, and that each resonator chooses from the mixture the wave whose period corresponds with its own. M. Cornu remarks on these experiments that Hertz's theory rests upon two bases—first, on the hypothesis that the discharges of the induction coil give rise to a disturbance of *fixed* period depending on the dimensions of the primary oscillator; and, secondly, on the *observation* of an *apparent periodicity* in the electrical state of the secondary conductor. The calculations by means of which Hertz obtains the period T of the primary oscillation are questionable, and the wave length λ is obtained by means of a resonator, on the assumption of analogy with elastic vibrations. The velocity V of propagation of the induction is then obtained from the equation $\lambda = V T$, and this velocity comes out in certain cases to be the same as that of light. The above experiments, according to M. Cornu, throw grave doubt on Hertz's theory, for they show that the oscillatory state of the secondary conductor, instead of being invariable, as would be an elastic column under the action of a single periodic force, depends essentially on the resonator employed. It is either necessary to conclude that the period T is not fixed and single valued, which is contrary to Hertz's hypothesis, or else V itself must be variable, which is absurd.

THE COAD BATTERY.

We inspected this week the Coad battery and concomitant apparatus at Mr. Coad's show rooms 31, Soho-square. The principal novelties claimed for it are, we understand, the solution, and the method of connecting up the plates. The solution is a secret—one might say that there is no novelty in this, as we have frequently heard of batteries brought out with secret solutions; but since the zincs amalgamate themselves, we may presume it is a solution of some mercury salt. There are two carbons in each cell, which rest against platinum pegs, tapped through the ebonite of the containing box; the zinc also rests against a similar platinum peg, the joining up being done by connections outside the cells, between the various pegs, the connections being afterwards all cemented in. Various forms of battery are on show, chiefly for mining purposes. In these latter the lamp is enclosed in an air-tight chamber under pressure, and arranged so that directly the pressure is relieved, by breakage or tampering, the circuit is broken. We were shown a battery weighing about 7lb., which had been running a (*circa*) one candle-power lamp for 17 hours, and which was still giving a good light. Mr. Coad makes use of a specially cut bull's-eye lens on these batteries, which appears to work well. We do not quite see, however, what advantages this has over an ordinary plain bull's eye, nor do we see why in his list Mr. Coad should speak of a battery with a one candle-power lamp and bull's eye as giving "10 candle-power" for ten hours. Mr. Gordon has given a very favourable report on the battery. As a battery to put in unskilled hands it is certainly a very well-arranged one, and apart from the local action due to the zinc being in contact with the platinum peg, in the liquid, the method of joining up is very convenient, allowing the use of plain carbon and zinc plates without any fixed connection on them.

MEETINGS OF SCIENTIFIC SOCIETIES, &c.

(To-night) FRIDAY, January 31st.

INSTITUTION OF MECHANICAL ENGINEERS.

7:30 p.m. Annual General Meeting.

ELECTRO-HARMONIC SOCIETY.

8 p.m. Smoking Concert at the St. James's Hall Restaurant.

ROYAL INSTITUTION.

9 p.m. Lecture: "Smokeless Explosives." By Sir FREDERICK ABEL, F.R.S.

SATURDAY, February 1st.

ROYAL INSTITUTION.

3 p.m. Lecture: "The Natural History of the Horse, and of its Extinct and Existing Allies." By Prof. FLOWER, F.R.S.

MONDAY, February 3rd.

ROYAL INSTITUTION.

5 p.m. General Monthly Meeting.

LONDON INSTITUTION.

5 p.m. Lecture: "A Visit to Mount Athos." By the Rev Prof. J. P. MAHAFFY.

SOCIETY OF ENGINEERS.

7:30 p.m. Ordinary Meeting. Inaugural Address by HENRY ADAMS.

SOCIETY OF ARTS.

8 p.m. CANTOR LECTURE II. 3. "The Electro-Magnet." By Prof. SILVANUS P. THOMPSON, D.Sc.

TUESDAY, February 4th.

ROYAL INSTITUTION.

3 p.m. Lecture, "The Post-Darwinian Period." By Prof. G. J. ROMANES, F.R.S.

INSTITUTION OF CIVIL ENGINEERS.

8 p.m. Ordinary Meeting. Paper to be read: "Bars at the Mouths of Tidal Estuaries." By W. H. WHEELER, M.Inst.C.E. Monthly Ballot for Members.

ROYAL VICTORIA HALL.

8:30 p.m. Lecture, "Algeria and Morocco." By HENRY BLACKBURN.

WEDNESDAY, February 5th.

CIVIL AND MECHANICAL ENGINEERS' SOCIETY.

7 p.m. Ordinary Meeting. Paper to be read, "Recent Progress in Sewage Treatment." By C. H. COOPER, A.M.I.C.E.

SOCIETY OF ARTS.

8 p.m. Ordinary Meeting. Paper to be read, "High-Speed Knitting and Weaving without Weft." By ARTHUR PAGET.

THURSDAY, February 6th.

ROYAL INSTITUTION.

3 p.m Lecture, "Sculpture in Relation to the Age." By EDWIN R. MULLINS.

LONDON INSTITUTION.

6 p.m. Travers Lecture, "The Law of Buying and Selling." By AUBREY J. SPENCER, M.A.

CHEMICAL SOCIETY

8 p.m. Ballot for the Election of Fellows. Papers to be read, "The Oxides of Nitrogen." By Prof. RAMSAY, F.R.S. "Studies on the Constitution of Tri-Derivatives of Naphthalene." By Dr. ARMSTRONG and W. P. WYNNE. "On the Action of Chromium Oxychloride on Nitrobenzole." By G. G. HENDERSON, B.Sc., and J. MORROW CAMPBELL, B.Sc.

FRIDAY, February 7th.

PHYSICAL SOCIETY.

5 p.m. Annual General Meeting. Papers to be read, "On Galvanometers." By Prof. W. E. AYRTON, F.R.S.; T. MATHER; and Dr. W. E. SUMPNER. "On a Carbon Deposit in a Blake Telephone Transmitter." By F. B. HAWES.

SOCIETY OF ARTS.

5 p.m. Indian Section. Paper to be read, "The Utility of Forests and the Study of Forestry." By Dr. SCHLICH.

INSTITUTION OF CIVIL ENGINEERS.

7:30 p.m. Students' Meeting. Paper to be read, "Reclamation of Land on the River Tees." By COLIN P. FOWLER, Stud.Inst.C.E.

ROYAL INSTITUTION.

9 p.m. Lecture: "The London Stage in Elizabeth's Reign." By HENRY B. WHEATLEY, F.S.A.

SATURDAY, February 8th.

ROYAL INSTITUTION.

3 p.m. Lecture: "The Natural History of the Horse, and of its Extinct and Existing Allies." By Prof. FLOWER, F.R.S.

The Electrician.

Published every Friday. Price Fourpence; Post Free, Fourpence Halfpenny
Editorial, Publishing and Printing Offices:

No. 1, SALISBURY COURT, FLEET STREET, LONDON, E.C.

Telephone No. 2714. *Telegrams:* "ELECTRICIAN NEWSPAPER, LONDON."

All Communications to be addressed to "THE ELECTRICIAN," *1, Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to* "THE ELECTRICIAN."

All letters intended for insertion in "THE ELECTRICIAN," *or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

"THE ELECTRICIAN" *is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.*

"THE ELECTRICIAN" *is on sale at the railway bookstalls throughout the United Kingdom on Friday morning, and can be obtained of all Booksellers and Newsvendors; or direct from the Publishing Offices as above.*

SPECIAL NOTICE.

Owing to the increase in the number of pages of "THE ELECTRICIAN," in order to partly cover the increased postage, we have been compelled to revise the rates for Foreign Subscriptions, which are now as follows:—

	3 months.		6 months.		12 months	
For Foreign Parts and Colonies:—	s.	d.	s.	d.	s.	d.
Within Postal Union	6	6	12	6	24	0
Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7	6	14	6	28	0
The rates for the United Kingdom remain as follows:—	5	0	10	0	19	6

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to the office.

TRADE ADVERTISEMENTS *intended for the current issue must be handed in not later than First Post on Thursday morning.*

SMALL PREPAID ADVERTISEMENTS *(for Rates see page xv.) are accepted up to 4:30 p.m. on Thursday.*

TECHNICAL PRINTING.

"THE ELECTRICIAN" PRINTING AND PUBLISHING COMPANY (LIMITED) *beg to inform Electricians, Electric Light Engineers, &c., that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

"THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK.

Royal 8vo.

Early in each year is issued "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1889 Edition consisted of more than 600 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with popularly-written Biographical Notices of the leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

The issue for 1890, which will be still further enlarged and improved, is in active preparation, and will be ready next week. Orders should be forwarded at once to the Publishing Office, **1,** *Salisbury-court, Fleet-street, London, E.C.*

TRAINING FOR THE ELECTRICAL INDUSTRY.

What shall we make of our boys? Some thousands of anxious parents who have pondered this problem during recent years have fondly imagined that they saw a brilliant solution of their difficulty in the new industry now growing up around the applications of electrical science. They had been assured by all their friends, legal, medical, clerical, mechanical and chemical, that all these professions were overstocked; whilst the manufacturers unanimously complained of the badness of the times. The anxious parent welcomed the suggestion of an electrical career, and his boy was forthwith set loose on the very first track which seemed to lead into the electrical industry. Three months in the laboratory and a month in charge of an electric light machine, and then forth stepped the full-blown electrical engineer blushing with consciousness of his novel dignity.

Such a rush to enter the new profession could not but bring about a serious reaction. Into no profession or industry is there a royal road that will summarily convert the inexperienced youth into an experienced adept. The training for the electrical industry, whether in its mer-

Digitized by Google

cantile or its professional aspect, needs to be just as strict, just as thorough, just as practical, as the training for any other industrial career. Let us consider what is wanted to make up the whole equipment of the electrical engineer. He must be, in the first place, an *engineer*, competent to deal with running machinery, with steam engines, boilers, shafting, capable of estimating for, and, if need be, of designing the same, and of undertaking their erection and management. He must be a mechanician, capable of devising and of constructing with his own hands the machine, or instrument, or tool that he requires. He must be a bit of a civil engineer, too, knowing something in a practical way about foundations and building construction. He must be thoroughly familiar with drawing-office work, including estimating from working drawings. He must, in the second place, be a thorough *electrician*, not merely an engineer with a skin-deep varnish of electrical knowledge. He must have acquired his knowledge of electricity not from books nor from men, but at first hand by having himself worked in the laboratory, in the testing-room, and in the dynamo-room, acquainting himself thoroughly with the thermal, mechanical, chemical, and magnetic properties of electric currents. As every engineer must be also to a fair degree a draughtsman, so must every electrician be also to some degree a chemist: he must have a working knowledge of the chemical properties of the materials with which he will have to deal. If, further, he proposes to fit himself for the manufacturing branch of the industry he must spare no pains to make his training as a mechanical engineer as perfect as possible, and must have as practical an acquaintance with the work of the pattern-shop, the foundry, the forge, and the fitting-shop, as though engines and pumps, instead of dynamos and electric motors, were going to be the products of his future factory. Lastly, for whatever branch of the industry he proposes to prepare himself, he will find that he will never have had time enough to acquire all the mathematics that he would have found useful in his work.

A formidable programme this for the furnishing forth of the budding electrical engineer; yet short of this none need expect to find himself rising to the top of his profession. He who is merely electrician without being trained engineer may indeed find a humble place in the testing-room of the factory; but a front rank in the industry is impossible for him. He who is merely engineer without being a trained electrician can never feel full confidence in or familiarity with his work, and will always be behindhand in the race for progress. The double training is essentially necessary: how to gain it is the real problem. No apprenticeship to a firm of engineers can give it; no college course, however complete or costly, can pretend to turn out the finished product. College training, if conducted not under schoolmasters, but under men who have themselves worked in their respective departments, may do much. It can train young men for the drawing-office, or for the testing-room; it may teach them the use of tools—even of machine tools to some extent; but college instruction is essentially imperfect in this respect: that however complete its equipment of laboratories and workshops may be (to say nothing of its lecture-rooms), however experienced the instructors who manage them, the work that is done in them is not being done under commercial conditions, nor under an organisation like that of a factory: it lacks, and must always lack, the stimulus of commercial enterprise. But if the college training is defective, so also is the system of apprenticeship in the shops. Nearly all large engineering firms derive a considerable income from premiums paid by the sons of wealthy parents, who are permitted, for a sufficiently large consideration, to enter the works and spend a few hours every day in company with the real workers. How many premium pupils eventually become competent engineers it is very difficult to ascertain: the percentage cannot be very high. Those boys who enter without premiums as bound apprentices have such long hours of labour, and so few chances of acquiring an all-round knowledge, that few of them can hope to become fully trained, unless by some unusual favouring circumstance they can add to their shop work a training in electrical laboratory work, in mathematics, chemistry, theoretical mechanics, and draughtsmanship.

The most desirable training is that which combines the respective advantages of both methods, which shortens the apprenticeship of the shops to two or three years, and adds two years of special training in the electrical laboratories of some one of those colleges which possess specially organised departments. It depends greatly upon the temperament of the young aspirant whether he should serve his apprenticeship in the shops immediately on leaving school, or whether he should take two years of laboratory training before he enters on his factory apprenticeship. For youths under 16 years of age probably the latter is preferable; whilst the former course is undoubtedly to be preferred for those who are older. For them apprenticeship in the shops must be now or never. If they wait till they are older they will never become good mechanics. We know that these views are shared not only by leading men in the profession, but by those who manage the electrical training establishments. Our best pupils, says one of the latter, are those who have knocked about, if even only for a year, in the shops; our worst are the fine gentlemen who come from the fifth or sixth form, and are afraid to dirty their hands.

Much as the various electrical schools and technical colleges have done for the progress of the electrical industries, they would do still more if they could make every one of their pupils realise that a college course can never supplant the apprenticeship of the shops, and can give but half a training—namely, that half which in turn the apprenticeship of shops will not and cannot afford.

OBITUARY NOTICE.

EDWARD ORANGE WILDMAN WHITEHOUSE.

We regret to announce the decease of Edward Orange Wildman Whitehouse, F.R.C.S., F.R.A.S., aged 73, which occurred at 19, Salisbury-road, Brighton, on Sunday last, the 26th January.

For many years Mr. Whitehouse took a great interest in all electrical matters. In conjunction with Mr. John Brett, who was the first concessionaire of the submarine cable between England and France, he was engaged in bringing out a telegraph instrument for printing in Roman characters. From early in 1854 he was almost exclusively occupied in experimenting, with a view to devising apparatus for working the Atlantic cable; and in 1856 he gave up a very large surgical practice at Brighton to devote the whole of his time to this object, being appointed electrician to the Atlantic Telegraph Company, his connection with which ceased on the failure of that company, and he again devoted considerable attention to many electrical devices, amongst others to electrical checks in connection with passenger fares in tramways and omnibuses. The last time he was professionally engaged in telegraphy was in 1861, when he was consulting electrician for Messrs. Glass, Elliott, and Co. during the laying of the Malta-Alexandria cable.

Mr. J. C. Laws, Mr. Frank Lambert, Mr. Joseph May, and Mr. H. A. C. Saunders, of whom only the latter survives assisted him in his electrical work from early in 1854 until his connection with telegraphy ceased, and he was also the cause of many others now well known in submarine telegraphy adopting that profession.

THE INSTITUTION OF ELECTRICAL ENGINEERS.

DISCUSSION ON THE PRESIDENT'S ADDRESS ON "MAGNETISM."

(Continued from page 291.)

The following is the authorised abstract of the adjourned discussion on Dr. Hopkinson's Presidential Address, which took place on Thursday, the 23rd inst.:—

Mr. SHELFORD BIDWELL, in re-opening the discussion, said the address was above criticism and required no comment, but as he was greatly interested in the subject himself, he wished to refer to the portion of the paper relating to the influence of stress on magnetisation. If a long thin iron wire be suspended vertically and subjected to longitudinal magnetising forces, its curve of magnetisation resembling Fig. 1 (*The Electrician*, January 10th, p. 246) is easily obtained. If now the wire be stretched by a weight, the curve of magnetisation rises more rapidly at first, but subsequently bends over and cuts the ordinary curve and remains below it as the magneting force increases. The point of intersection is known as the *Villari critical point*, and the change in the relative permeability is called the *Villari reversal*. Converse effects were obtained by Joule in 1840, who showed that a bar is lengthened by magnetisation until the magnetising force reaches about 120 C.-G.-S. units, when no further elongation was observed. Joule's experiment has often been repeated, but until comparatively recently no one seems to have used much greater magnetising forces than those originally employed. The speaker, however, has subjected wires to forces of 800 or 1,000 C.-G.-S. units, the results of which are shown in the diagram Fig. A. From this it will be seen that for forces above 100 the elongation diminishes as H increases, and eventually magnetisation shortens the bar. Similar curves for nickel

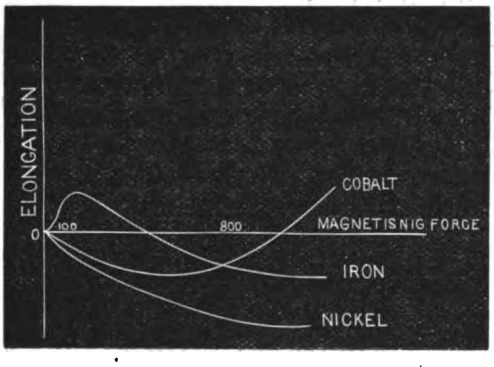

FIG. A.

and cobalt are given in the same diagram. In his "Applications of Dynamics to Physics and Chemistry" Prof. J. J. Thomson has shown the elongation and retraction of iron to be closely connected with the Villari reversal, and applying a similar argument to the properties of cobalt, Mr. Bidwell predicted that this metal would present a Villari reversal of an opposite character to that observed in iron; but on trying the experiment the reversal was not found. Probably, however, he had misunderstood Prof. Thomson's argument, for quite recently the latter had predicted a Villari reversal when cobalt was compressed, and this was verified by experiment.

Prof. ROBERTS-AUSTEN stated that there were, from the point of view of a metallurgist, several points in the admirable address to which he wished to direct attention. The President has said that wrought iron on cooling does not evolve heat as carbonised irons do. Prof. Austen, however, reminded the Society that electro-deposited iron (which is pure iron) does on cooling down from 1200°C. evolve heat suddenly when the temperature falls to 858°C. This points to a distinct molecular change in the iron itself wholly unconnected with the presence of carbon. The President, he said, only appeared to recognise a single critical point at which heat is evolved, and to that he always applied the name of "recalescence." Osmond has, however, shown that there are at least two perfectly distinct phenomena which may be observed in cooling masses of iron. First, there was the transformation of hard β iron into soft, or α iron; and, secondly, the "recalescence" of Barrett. Referring to Dr. Hopkinson's remarks on the "double recalescence of soft steel," he said that the two distinct evolutions of heat were due to totally different causes, and not to any want of uniformity in the mass. As regards the President's statement that the magnetic properties of iron "appertain to the *molecule* and not to the *atoms* of the mass," Prof. Austen asked, Is it a great step from this to admit that more than one kind of iron can exist? Normal iron may, he urged, under certain conditions, pass into an allotropic form, in which the arrangement of the atoms in the molecule is different from that of ordinary iron; and the physical properties of these two kinds of iron are as totally distinct as those of the allotropic modifications of sulphur and phosphorus are from those of the elements in their normal forms.

Prof. S. P. THOMPSON said the behaviour of the nickel-iron alloy reminded him of a specimen of natural alloy of the same two metals shown to him some years ago by M. Becquerel. This differed in its magnetic properties from Dr. Hopkinson's samples, for although it was non-magnetic when first obtained, it became magnetic on being heated and allowed to cool. Alluding to the supposed instability of iron, as mentioned by Prof. Ewing, Dr. Thompson said that in a Paper on the Mechanism of Magnetisation, Chwolson* had arrived at some very interesting results. The experimenter endeavoured to distinguish between temporary and subpermanent magnetism, and his curves show that the former increases regularly at first and afterwards more slowly, whilst the latter makes a sudden rise when the magnetising force reaches a certain value, and afterwards remains nearly constant as the force increases. The sum of the two effects gives the usual magnetisation curve (*see* Fig. B). Referring to the question of "permeability," Dr. Thompson described a simple apparatus for measuring that quantity which he had recently devised for workshop purposes. This consists of a slab of good iron having a rectangular hole through it. One end of the hole is truly surfaced, and at the other end a hole is drilled in the plate parallel to the length of the rectangle. Through this hole the rod to be tested is inserted, and its faced end rests on the plane surface at the bottom of the rectangular hole. A current is then sent through a solenoid surrounding the test rod, and the force required to detach the rod from the surfaced end is measured by a spring balance. The permeability is then calculated from the formula

$$\mu = \frac{1317}{H}\sqrt{\frac{P}{A}},$$

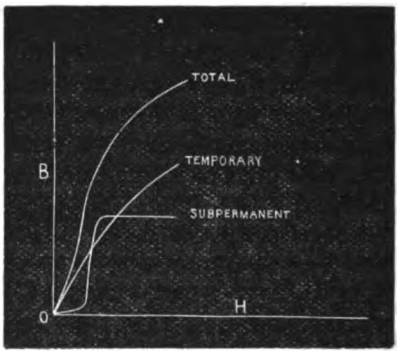

FIG. B.

where H is the magnetising force used, P the force of detachment in lbs., and A the area of the rod end in square inches.

Prof. AYRTON asked Dr. Thompson whether the character of the surfaces in his contact affected the results obtained by his new apparatus. He also said the curves for temporary and subpermanent magnetism referred to by the same speaker were very interesting, and had a practical significance in the construction of electrical measuring instruments in which soft iron is used. Speaking of the magnetic properties of iron at high temperatures, he inquired whether the President had tried if these properties were regained at a white heat, for he remembered reading a pamphlet by Dr. Wormwell that such was the case. On roughly trying the experiment, by heating a piece of iron in a blow-pipe flame, and bringing a magnet near it, he had only found one out of three pieces to give any signs of magnetisation, and of this he was not quite certain. Another question on which he desired information was an apparent anomaly in the magnetisation of two iron rings, which he had constructed some years ago from the same bar, and annealed together. One ring is continuous, whilst the other is divided at one point by a narrow slit. On determining their magnetisation curves, the induction in the divided ring is found to be considerably below that in the whole one for low values of the magnetising force, but for large forces the induction in the cut ring is decidedly greater than in the uncut one. Another curious effect with the same rings and which has hitherto remained unexplained, is that the deflection of the ballistic galvanometer caused by changing the magnetising current from +A (amperes) to −A is different from that produced by changing it from −A to +A, and this difference remains however many times the reversals are made.

Mr. SWINBURNE, alluding to Weber's theory of magnetisation, inquired if any experiments had been made with the object of

Pogg. Ann. (Ergänyunland), VII., p. 535.

Digitized by Google

setting the axes of all the magnetic molecules parallel, and thus reducing the angle of the cone within which, for a given magnetising force, they must all be. As a method of doing this he suggested that a wire be subjected to longitudinal and circular magnetisation simultaneously. Referring to the terminology of the subject he said the word "magnetisation" generally conveyed very vague ideas to the average mind, and thought its use should be avoided.

Mr. PREECE described the methods of testing magnet steel used by the Post Office authorities, and promised to add a table of tests to his remarks as printed in the *Journal*. The tests are made by two methods: first, by determining the force required to detach an armature; and second, by the magnetometer method. A great improvement, he said, was made in the magnetic quality of steel by the addition of about 3 per cent. of tungsten, the influence of which was brought into prominent notice by the Alvane steel exhibited at the Paris Exhibition in 1881. Speaking from the records of the Post Office tests, he was sorry to say that the quantity of magnet steel is seriously deteriorating, for in 1883 steel giving a permanent induction of over 5,000 C.-G.-S. units was obtainable, whereas in 1886 this had fallen to 3,700. Recent tests show a still further deterioration, for one specimen gave 2,320, another 1,948, and a third 1,411. The subject, he thought, required the careful attention of manufacturers, and he hoped that immediate steps would be taken to improve the quality of magnet steel. On examining the numbers obtained by Continental observers, he found that the maximum value had been obtained by Kohlraush, and was 3,900. Mr. Preece also directed attention to an article by Prof. Trowbridge in the current number of the *Phil. Mag.*, which gives particulars of an alloy of nickel and tungsten.

Mr. EVERSHED confirmed Mr. Preece's remarks on the deteriorating quality of magnet steel, and said that in testing magnets he found it very convenient to use a test coil and galvanometer. Referring to nomenclature, Mr. Evershed said he was one of those who thought there was no need to use the word magnetisation in its present ambiguous sense, and that the ideas of polarity, magnetic moment, free magnetism, &c., were not required, except (perhaps) for permanent magnets. Even with these, m, now that the President has given a definite meaning to "coercive force," the value of H, together with the permeability, seemed to him to give all the necessary information. He also thought the word "induction" should be defined to mean what is generally called "total induction," and a new name should be given to density of induction, or induction per unit area. For some time past he and his colleague, Mr. Vignoles, have been in the habit of using the word "Thomson" to denote a line of force, but they would be quite willing to adopt any other name which would meet with general approval. Quite recently he had been engaged with Mr. Vignoles in investigating the properties of iron when subjected to magnetic cycles, such as occur in transformers, and had found it a great convenience to wind the transformer with two primaries. In one of these a constant current is maintained, and the whole cycle is obtained without reversing the testing current in the other coil. Speaking of the instability referred to by Prof. Ewing, Mr. Evershed said their results gave no indication whatever of such a phenomenon, and as to the effect of vibration, they found that a good blow with a hammer only produced a change of about 2 per cent. at the most sensitive part of the curve. Prof. Ewing's results, he ventured to think, might be due to want of endlessness in the specimens tested.

Some discussion took place between Profs. AYRTON, THOMPSON, and PERRY, and Messrs. EVERSHED and VIGNOLES as to whether there was any advantage in having two primaries on the transformer used in the experiments on magnetic cycles, but no very clear understanding was arrived at, excepting that the latter gentlemen considered it much more convenient to change the magnitude of a current than to reverse it.

Mr. A. P. TROTTER asked the President whether the sample of nickel iron alloy whose properties were represented in Fig. 9 (*The Electrician*, January 17, p. 271) was unique, or whether other alloys have been found to give similar results. The remarkable peculiarities of this specimen suggest the possibility of copper, lead, &c., being cooled low enough to become more magnetic than Mr. Preece's magnet steel.

The PRESIDENT, in replying to Sir W. THOMSON'S remarks on recalescence, said that in heating the metal a considerable absorption of heat occurs at about 30°C. above the temperature at which recalescence takes places on cooling, but his experiments proved that the changes in the magnetic properties follow precisely the absorption and liberation of heat both in ascending and descending. Referring to Prof. Ewing's remarks on what he called "hysteresis of nickel steel," shown in Fig. 9, Dr. Hopkinson said he thought the word hysteresis not very appropriate when applied to this phenomenon, for he considered the peculiarity more analogous to change of state from liquid to gas or *vice versâ*—as in the case of water, for example, these changes can be considerably retarded by adopting suitable precautions. Prof. Roberts-Austen had, he said, alluded to the liberation of heat when iron changed from the non-magnetic to the magnetic state. The phenomena accompanying this change seemed to him (the President) to be analogous to "boiling with bubbling," where the temperature of the liquid is first raised considerably above the boiling point, and a sudden liberation of vapour brings down the temperature. As regards Prof. Ayrton's question relating to the return of the magnetic property at high temperatures, he could only say that he had not observed it, but the greatest temperature attained in his experiments was about 950°C. To experiment at higher temperatures was a very difficult matter, for copper is then near its fusing point, and platinum cannot be used, because at this temperature it decomposes the silica of the asbestos used to insulate the magnetising and test coils. He could not offer any explanation of the observations on the iron rings described by Prof. Ayrton, and for the present must regard them as anomalous. Referring to the revision of terminology suggested by several speakers, Dr. Hopkinson thought there was no necessity for this, for the terms "pole," "magnetic moment," &c., were most convenient when talking of permanent magnets, whilst "induction" and "permeability" were preferable when the magnetisation of iron was under discussion. In reply to Mr. Trotter, he said that many other alloys had been tried, and one specimen of mixed steel containing five per cent. of nickel gave very similar results to that shown in Fig. 9, but the range between the critical temperatures was considerably shorter, these temperatures being 650°C. and 800°C. respectively. The same sample tested for recalescence was found to absorb heat at about 800°C., and on cooling heat was liberated about 650°, thus showing the close connection between these phenomena and magnetisability. Since last meeting he had tested the variation of specific resistance of nickel steel with temperature, and found that a considerable reduction was produced by cooling it in solid carbonic acid. On heating, its resistance increased slowly and uniformly at first, and afterwards with increasing velocity, until

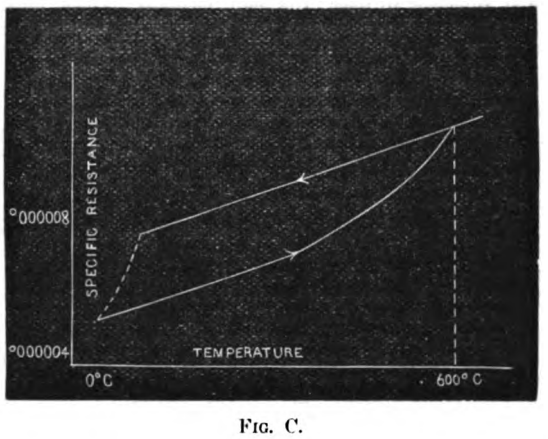

FIG. C.

a temperature of 600°C. was reached. At this temperature a sudden change occurred, and the resistance increased more slowly and uniformly as the temperature rose. On cooling the specimen its resistance fell uniformly, until at the ordinary temperature it returned to its initial value. The whole cycle could be repeated by again cooling in carbonic acid and proceeding as before. Fig. C shows diagrammatically the character of the change. Other samples were tested for tensile strength, and when in the ordinary state gave an average breaking stress of 50 tons per square inch, with an extension of 30 per cent.; specimens which had been chilled broke at 85 tons, with an extension of only 8 per cent. This fact, he said, was of vast importance from an engineering point of view, for if such changes in the nature of a mild steel were brought about by its being subjected to a hard frost the consequences would be very serious if such a metal were used in structures.

THE ELECTRICAL TRADES COMMITTEE OF THE LONDON CHAMBER OF COMMERCE.

A meeting of the members of this body was held at Botolph House, Eastcheap, on Monday, Mr. R. E. Crompton presiding.

The SECRETARY (Mr. Kenric B. Murray) having read the minutes of the previous meeting, and the report of the correspondent for the intervening period,

The CHAIRMAN said that, as all the members knew, the Chamber had been taking considerable pains to make the forthcoming Electrical Exhibition at Edinburgh as popular as possible, but in spite of all their efforts they had not succeeded in doing so. If any gentleman had anything further

Digitized by Google

to say as to what he thought should be the duty of the Committee under the circumstances, the members would be glad to hear him. He (the speaker) thought it was a very good proof of the surfeit that they had recently had of exhibitions, that nobody seemed to be in the least interested in the one to be held at Edinburgh.

Mr. PRICE said that reports were being very diligently circulated in every paper that the whole of the space at the Exhibition had been applied for three times over.

Major FLOOD-PAGE remarked that he had been abroad for some weeks, and he had not had any communication from Edinburgh, but he had heard that the French Government had recognised the Exhibition, and that the Exhibition authorities were going to accept the French Government's electrical exhibits, paying all the expenses of bringing them over; and he also heard, what Mr. Price had just said, that there was to be a very large number of exhibits at the Exhibition, and that it was going to be a great success.

The CHAIRMAN asked whether, under the circumstances, it was the pleasure of the members to do anything further in the matter.

Major FLOOD-PAGE suggested that they might ask the Exhibition authorities for a list of the promised exhibits. When he was in Berlin the other day he heard that a very large German organisation was going to exhibit in Edinburgh.

Major Flood-Page's suggestion was then agreed to.

The CHAIRMAN said that the next subject on the agenda paper was with regard to the British Association screws. Mr. Trotter and himself had taken some trouble in the matter, because they thought it was a very useful thing for the Section to take up. Their great wish was to have a universal screw adopted by the electrical trade, and he thought they could get the trade to accede to their wishes. The way they proposed to set about the work was this: Mr. Trotter would find out by means of a circular letter the size of the screws the trade were mostly using. They then proposed to obtain alternative estimates for 25 or 100 complete sets, not only of the standard screwing tackle, but to send out a few dozen of each kind of screws in use, so as to let people test their comparative merits. When they found out what the cost of that would be, they would send round the hat for subscriptions in order to get a guarantee fund sufficient to meet the cost incurred. Their object was to distribute and make thoroughly known the standard screwing tackle and the sets of screws. What he was anxious to know was whether the game was worth the candle to make it their object to get a standard screw. What he was going on to suggest, if it pleased the Committee to proceed with the matter, was, that a small committee, consisting of one or two members besides Mr. Trotter and himself, should be appointed to try and find out the wishes of the trade in general on the subject.

Mr. J. SWINBURNE proposed and Major FLOOD-PAGE seconded a resolution giving effect to the recommendation.

The CHAIRMAN then went on to say that the question of the County Council surveyors and their dispensing powers had been brought before him some time ago. It affected the whole of the electrical trade which had anything to do with the construction of buildings for electrical stations in London. Every building in London had to be put up under the Metropolitan Building Act, which had been always unworkable for honest people, but had been a very good means of sheltering the "jerry" builder, and of putting difficulties in the way of those who wished to make changes and improvements in their property. The complaints from architects on the subject were very wide and deep indeed. In the days of the Metropolitan Board of Works the grievance did not press very hard, because in those days they looked to their district surveyor, who was entrusted with certain dispensing powers, and who made it his business to see that he had to deal with a good architect and an honest contractor, so that very little harm resulted from that practice. But the new County Council had determined to take away all such dispensing powers, and the result had been a dead-lock. He was not very conversant with the Act himself, and so he had got Mr. Slater, an architect who had done a great deal of work on central stations, to give his help in the matter. The object of the architects in appealing to the Chamber on the subject was that, as they themselves as a body were about to petition the County Council to bring in a Bill for the amendment of the Act, they thought if other trades would petition the County Council as well, the purpose which they were aiming at would be accomplished. He then read a letter from Mr. Slater fully setting forth in detail the grievances which owners of house property now suffer under the Metropolitan Building Act.

Major FLOOD-PAGE said that there could be no doubt that the subject was one of very great importance, but it seemed to him that they were hardly the Section to take up the reform of the Metropolitan Building Act. It was a very big question, involving the complete recasting of that Act, and it was one which the Section could not by itself possibly deal with. They had the very great advantage that the Chairman of the Chamber was also deputy-chairman of the London County Council, and they would therefore have a very good chance of getting what they wanted carried out. He would therefore move—

"That the Chairman of this Section be requested to draw the attention of the Council of the Chamber to the inconvenience to this Section of the Metropolitan Building Act, with a view to their consulting all the Trade Sections interested in the matter, with the ultimate intention, if the Council approve, of bringing the subject before the London County Council."

Mr. WHARTON seconded the resolution, which the Chairman put to the meeting, and declared carried.

The CHAIRMAN said that now that the Chamber had been the means of bringing them a great deal together his object was to try and see if they could get as much mutual benefit out of it as possible, and he wanted to propose, in the most timid way to commence with, that they should try and see how far they could benefit one another by contributing useful information on the subject of producing electricity. There was no doubt that in certain trades this interchange of information had been extremely useful. As an example, he instanced the iron and steel trade. The great developments of the steel trade arose from the early meetings of the Iron and Steel Institute. He thought it would be too much to hope for similar results in the electrical industry, but he was of opinion that there was a great deal of information that they could safely communicate to the Section, and that others would be willing to contribute, out of which common fount of knowledge they might all learn something useful to them in their profession. They could, for instance, easily commence in the case of the central supply companies by asking them to furnish the Chamber with something more than the Board of Trade demanded in the shape of annual accounts and certain analyses of those accounts. He had no doubt some companies would refuse to comply with the request, but he could hardly think that those companies would gain by so doing. If they could not only obtain the accounts of all the supply companies at the present time in this country, on the Continent, and in America, but form themselves into an association for distributing the information so obtained, he believed every one in the profession would be willing to join the association, and would unanimously benefit thereby. He was sure that from the statistics they would thus obtain, one man would be able to find out if he were using too much coal, another would discover if he were paying too much in wages, a third would be able to see if his system of distribution were equal by comparison to that of other people, and so on. He could see great difficulties in the way of persuading some people, but he knew that many others would join, because several gentlemen had offered to submit the figures of their companies to himself. He now wished to sound the Section if they thought it would be possible to start such an association. His idea of starting it would be to write not only to the companies in England, asking them to fill up, as far as they pleased, a certain standard form of analysis of accounts, but to the principal companies in America, desiring them to do the same thing. He believed that they would gradually attract more and more to them all those who were really desirous of effecting improvements in the way of producing electricity cheaply.

Mr. SWINBURNE asked what would be the conditions of membership.

The CHAIRMAN thought that there might be a certain defined number of subscribers, from whom it might be necessary to take a small money subscription, which would entitle them to a copy of the *data* furnished. The figures might be compiled in America, England, and Germany by sub-sections.

Mr. SWINBURNE asked whether they would extend their inquiries beyond central stations.

The CHAIRMAN said it should be the wish of all to cheapen the manufacture and distribution of electricity, and everybody he thought should do his best to that end.

Major FLOOD-PAGE thought they would all sympathise with the motion underlying the remarks of the Chairman, but he believed it was hardly possible to exaggerate the difficulty—he was going to say almost the impossibility—for some time to come at any rate—of arriving at what the Chairman was aiming. For example, he had no doubt whatever that many companies would say that it was absolutely impossible for them to give more information to any public body than they could to their own shareholders. That would be an initial difficulty not lightly overcome. Then, again, he had been over some works in Germany within the last few weeks, and he was perfectly certain that the information the Chairman was seeking would not be supplied. If ever they arrived at practically only one system of working electrical companies, as in the case of gas companies, there would be perhaps no difficulty in the way. But he would suggest whether one preliminary step would not help them forward in the proposed direction, namely, to write to all existing companies asking them to send to the Chamber a copy of their reports with their accounts. That would in itself be a practical step, inasmuch as the published accounts were, to a certain extent, public property. There would be no objection on the part of managers or directors to supply the published accounts. Having got all the information together, they would be able to analyse it, and get one step at least in the direction suggested by the Chairman.

The CHAIRMAN said he would like to set their minds at rest on one particular. The point most interesting to them—the cost of producing electricity—was not the whole of the cost. It was a very small portion of it. The other things that made up such a large item of the expenditure were chiefly connected with the working of the companies, and so forth. The cost of producing electricity in a station itself and distributing it did not form a very large part of the whole, and did not let out the secret of the dividend that was going to be paid. That was the reason why the iron and steel people had been able to send out the returns of their blast furnaces, showing how much coke they used, and so on. The ordinary shareholder could not know how many tons of coal or coke were required for making a ton of iron, but if he were a member of the Iron and Steel Institute he could know. Shareholders as a body were not interested in the kind of knowledge he sought to obtain. He was perfectly satisfied that the United States would exchange information with them at once.

Some further conversation took place on the subject, and in the end it was agreed that the Chairman should draw up the draft of a circular letter to be sent to the various companies, asking for the desired data, and submit it to the next meeting of the Section for discussion.

The proceedings then terminated with the usual vote of thanks to the Chairman.

THE PHYSICAL SOCIETY.

At the meeting of this Society, held on the 17th inst., Prof. S. P. THOMPSON read a Paper on

"Electric Splashes."

The author stated that he had been engaged for a considerable time in experimenting on the curved figures, generally known as Lichtenberg figures, which are produced by means of electrical discharges on the surface of a non-conductor dusted over with a mixed powder, electrified by shaking. He was anxious to find the cause of the difference of form of the figures formed by the positive and negative discharges respectively. The first questions which presented themselves for solution were whether the character of the figures was dependent on the nature of the non-conducting surface, of the powder, or of the surface from which the discharge was taken.

The results of the experiments showed that neither the nature of the powder nor that of the non-conducting surface had any perceptible effect on the character of the figures produced; but the character of the figures obtained did partly depend on the size, shape, and amount of polish of the conductor from which the discharge was taken. He had discarded the usual mixture of red lead and sulphur, because the red lead was so heavy that the motions of the particles under the action of the electrical forces were very considerably disturbed by the action of gravity; and he had replaced it by a mixture of sublimed sulphur and powdered lycopodium, which he found to answer exceedingly well. The figures were found under some circumstances to have outlying portions which looked so much like splashes that he had called them "electric splashes." The best non-conducting surface he found to be a cake of pitch or resin, which had been completely discharged by passing a flame over its surface immediately before making the experiments.

The author then proceeded to discharge a large cake of pitch in the manner described, after which the knob of a large Leyden jar, first charged positively to a high degree, and then to a high degree negatively, was drawn over the surface, which was then dusted with the mixture of sulphur and lycopodium, giving the well-known Lichtenberg figures with remarkable distinctness. The experiment was then repeated with the alteration of not allowing the knob to touch the surface, when some well-marked splashes were obtained; but many of them were of imperfect shape, owing, as the author explained, to the wind from the points of roughness of the knob, which was not sufficiently well polished.

The author found that the negative figures were more readily spoiled in shape than the positive ones, which was in accordance with the generally admitted fact that a negative charge is more easily dissipated than a positive one.

DISCUSSION.

In the discussion which followed the reading of the Paper,

Prof. RÜCKER stated that he had recently been engaged upon experiments of a somewhat similar character. He had repeated the ordinary experiment of sending a discharge just over a sensitised photographic plate, and had also drawn the knob of a jar over it, and in both cases the marks obtained were of the character expected, viz., the negative ones were rounded while the positive ones were branched. The whole question was one of the greatest importance. In sending a discharge across a lampblack plate he had obtained sparks with black and white cores respectively, according to whether the discharge was taken from a positively or negatively charged body.

Prof. W. G. ADAMS considered Prof. Thompson's experiments to be most interesting, and they would be of the very greatest importance if they led to an explanation of the greater ease with which a negative charge escapes compared with a positive charge.

INSULATION IN MARINE WORK.*

The secret of all success in electric lighting, and especially aboard ship, is a good, durable, and well-protected insulation. In the early days this fact, if recognised, was not fairly considered. To-day, and thanks in a large measure to the office of the Naval Inspector of Electric Lighting, established in 1887, not only the installations in the cruisers now building, but from competition amongst manufacturers, drawing their inspiration from the requirements of that office, commercial plants as well, give evidence of increased excellence in this regard.

It does not seem to be difficult to manufacture an insulation that will answer all requirements when new. The great trouble has been to obtain durability when subject to the varying conditions of heat and cold, dryness and moisture, and the rough treatment incidental to use aboard ship. Vast quantities of materials have been brought into requisition, such as resins, which are usually too brittle, or when mixed with tar too easily softened by heat, allowing the conductor to sink through; asphaltum and bituminous compounds, which have been favourably mentioned; tar and pitch, not regarded as trustworthy when used with rubber or gutta-percha, the latter suffering injury from the action of the solvent oils; paraffin, which shrinks on cooling, and tapes soaked in the latter, which are rotted by the free acid; asbestos, which resists heat and the action of acids, but absorbs moisture; ozokerite, a crude native paraffin, originally like petroleum, but from which the more volative components have escaped, found in Galicia, lately in Utah, applied in various ways to rubber, supposed to shorten the life of the latter; cotton, silk, flax, and jute, with or without shellac or paraffin, which do not withstand changes of temperature or moisture; gutta-percha, better than most of the above, but must be kept under water or at a uniform temperature, hence, unsuited to ship's use; and lastly, indiarubber, well-nigh universally recognised as the most desirable material, but on account of its comparatively high cost not used to a considerable extent in its pure state, but more or less adulterated with many of the above-mentioned substances. In this brief list no mention has been made of the numerous patented compounds, which possess greater or less excellence according to the cost and care of their manufacture and the use for which they are designed, but it is safe to say that not one of them equals in insulating properties and durability, under the changing conditions, pure indiarubber, but in the struggle to obtain a cheaper commercial article approximates to it in excellence more or less in the ratio of its cost.

The qualities recommending pure rubber are its high insulation, its durability, flexibility, elasticity, its power of withstanding changes of temperature and moisture, and its immunity from the harmful action of most acids. There are, of course, cases in which it is not necessary to use pure rubber for the whole thickness of the insulation. For large conductors, such as are used for electric lighting, it is sufficient to have a layer of pure rubber to begin with, and vulcanised rubber compounds and tapes outside. In all cases it is necessary to prevent access to the copper of the sulphur of vulcanisation, as the former would be thereby soon attacked and corroded. Likewise the pure rubber must be protected from any possible heating of the conductor when accidently traversed by strong currents. These objects are attained in the best wire of to-day, as follows:—The copper strands are covered with a heavy, smooth, and a uniform coat of tin. The latter metal resists most of the chemical actions that would injure the copper. The conductor, of a single or several twisted strands, is then wrapped with a thoroughly dried cotton parcelling, or is braided with cotton, and is soaked in a pure rubber solution. After that comes a ribbon or sheet of pure rubber, technically called brown rubber; then a layer of rubber containing no sulphur, usually mixed with zinc oxide, and called the white rubber or separator; then a layer of vulcanised rubber, called black rubber, or a layer of Okonite, and lastly, a cotton parcelling, or preferably a braiding, soaked in ozokerite or some insulating compound. A disadvantage of having cotton next the wire is that it collects moisture. This may be prevented by having it thoroughly dry when put on and applying the pure rubber at once in a dry atmosphere. An incidental advantage is that it keeps the surface of the wire clean and bright. The real reason for its use, however, is that it keeps the pure rubber from softening when the conductor is overheated. Para rubber is the best and purest form in use, and is stipulated in the latest navy contracts. The outer layer is vulcanised to render it more durable, and the white rubber separator prevents the sulphur from penetrating. A lead covering is now generally used in ship lighting. It must be pure and soft to stand bending, and thick enough to resist abrasion. Its object is to prevent access of salt water to the conductor, and to permit the whole system to be made water tight. An incidental advantage is that it prevents to a great extent the drying and cracking of the insulation. Tin is sometimes alloyed with the lead in underground conductors, and is said to render it less liable to oxidation and pitting. A covering of jute gives it additional protection.

It is not to be supposed that such insulation as this was manufactured a few years back. It will be interesting to follow its development as shown in plants so far installed in ships of the navy. The "Trenton" was the first man-of-war lighted by electricity, and was installed by the Edison Company in the summer of 1883. The specifications required that the conductors should be of the most improved pattern used by the Edison Company for isolated lighting. The present inspector of electric lighting supervised the installation in a general way and served as executive officer of the ship during the ensuing cruise. The company, however, was primarily responsible for the material, having ample latitude under the contract. It is safe to say that they supplied the best insulation at that time to be had in this country, though fears were entertained of its ultimate adaptability to the requirements of shipboard. The conducting mains were of a single strand of copper in two sizes, Nos. 12 and 14 B.W.G. The larger wire was covered with three braidings of cotton, the inner one soaked in bituminous compound, and the outer one painted. The smaller wire was wrapped with cotton thread, soaked in a compound, then braided with cotton and painted. Neither of these insulations proved efficient. The first answered fairly well, but principally owing to the protection afforded by well-painted wooden mouldings enclosing the wire. The second frequently gave out, softening, and allowing salt water to reach the wire. The branch wires for single lamps were of two sorts, both No. 18 B.W.G., one tinned and rubber-coated, the other similar to the No. 14 above. The rubber was of poor quality, broke off, and did not stand heat. The coating of tin, however, prevented the access of salt water and consequent corrosion. On that account it was recommended in the future to tin thoroughly all wires for ship lighting. The other branch wire proved worthless, and had to be replaced during the cruise. The vicious effects of salt water seemed so apparent that a lead covering for all wires was recommended. Thus it is seen that this plant, while in the main successful, afforded valuable lessons for future guidance.

It will be proper here, in point of time, to mention two installations,

* From the *Electrical Review* of New York.

Digitized by Google

both by the Edison Company, which, while intended to be the best, were not directed by the Bureau of Navigation, and were not on the lines of the experience gained in the "Trenton." The first was the "Dolphin," in the summer of 1884. The building contract required her to be lighted by electricity, and the contractor was at liberty to select any system. The conductors employed were of copper, tinned, insulated with rubber tape. In the smallest size a painted cotton covering took the place of the rubber tape. Mouldings were not generally used, but in some cases a light batten was employed for appearance or for protection from salt water. This type of conductor has proved fairly satisfactory. In some cases water has reached the wire with the usual corrosive effect, though the faults were stated to be due to improper leads and carelessness in wiring rather than to the character of the insulation. It was recommended to paint the parcelling.

The other installation referred to was that of the "New Hampshire," in the autumn of the same year. Her mains were of No. 16 double conductor wire. Each strand was first parcelled with cotton and served with thread, and the whole soaked in melted paraffin. The two were then wrapped together with rubber tape and thread and again paraffined. The idea of this poor insulation of the mains from each other was that in case of a fault or short circuit, before the current could do much damage, the insulation would be heated and perforated, the conductors would come together, act as a fuse, and the circuit would be broken. This system was not successful in practice. Safer and more economical means can be devised to accomplish the same end. For the branch leads, two sizes of wire, Nos. 17 and 18 B.W.G., both tinned, were employed. The former was rubber insulated and parcelled with tape, and proved the most satisfactory of the installation. The other was insulated with gutta-percha, which, as has been seen, does not stand change of temperature, is brittle when cold, cracking and breaking, and soft when hot, allowing the wire to sink through. No mouldings were used; salt water penetrated the insulation and corroded the wire. The double conductor mains were shortly replaced by torpedo wire. In the spring of 1888 the ship was entirely re-wired with Okonite wire laid in wooden mouldings. It is reported to give satisfaction.

In the summer of 1884 specifications were got out for the "Atlanta," "Boston," and "Omaha." They were identical in requiring the conductors to be of copper wire, tinned, insulated, and laid in pure lead tubing. The "Omaha," installed by the Consolidated (Sawyer-Man) Company, was the first completed, in the spring of 1885. The two sizes of conductors were used, Nos. 6 and 16 B.W.G., consisting of a single strand of copper, tinned, insulated with two layers of cotton braiding soaked in paraffin and lead-covered. They were secured by iron staples and were generally without the protection of moulding. The first reports on this wire were favourable. In the latter part of 1887 leaks were first noticed, the lead having been found cracked and the wire corroded. In the beginning of 1888 the ship was recommissioned for another cruise and large quantities of new material sent out to replace the old. The new wire was rubber insulated, lead covered, and similar to the best samples of the time, to be described later. In regard to the old wire then in the ship, that on the spar-deck and engine-room circuits was described by the officer in charge of the plant as completely useless. The lead covering had been cut through by the staples, the cotton insulation rotted by salt water, and the wire grounded. It was considered that a lead covering, on account of the facility it afforded for grounds, was not desirable except with perfect insulation, and iron staples, it was thought, should never be used. In the latter installations the practice has been to use a flat fibre staple to secure the lead-covered wire in the mouldings. The material is tough and elastic, and is not affected by salt water. Specially devised instruments are employed to puncture holes for them in the wood and to set them home; they do not stand driving with a hammer. The driving tool should be constructed in such manner as to prevent setting home too hard and thereby cutting the lead.

Next we come to the "Atlanta," installed by the United States Company (Weston system) and finished in the autumn of 1886. Two sizes of wire were used, Nos. 10 and 18 A.W.G., each a single strand tinned, wrapped with thread, covered with a preparation of rubber, a paraffined braiding, and a lead coating. This wire answered for a while. The first report of broken lead, entrance of salt water and corrosion was in the second quarter of 1888. The trouble occurred in the after orlop, though other portions must have been more exposed. It is an instance of how salt water finds its way everywhere. Portions of this wire subjected to continuous heat over the wire gave evidence of a thorough baking and disintegration of the insulating materials. The process of vulcanisation is apt to go on under these circumstances till all the rubber is a solid mass. The separator and pure rubber must be depended on to stop the injurious action. In 1887 samples of Okonite wire, with and without lead cover, were received for trial. These samples were of the same size as the original conductors, had a layer of Okonite next the tinned wire, and a braiding soaked in an insulating compound.

The "Boston" was installed by the Brush Company, and finished in the spring of 1887. The wire supplied was like the "Atlanta's" in every respect. In the third quarter of 1887 it was reported that salt water got to the wires where passing through the steel decks. Bad insulation was assigned as the cause. During the installation of these two ships they were inspected from time to time by the present naval inspector, though the specifications and contracts were made before the establishment of his office. Their plants were certainly superior to any previously installed, and, in spite of the faults enumerated, fairly efficient.

The next wiring to be considered is that of the "Chicago," installed by the Edison Company, contracted for in December, 1886, and finished in the spring of 1888. The specifications required that the conducting wires should be tinned, covered with the best rubber insulation, and enclosed in pure lead tubing. A sample of not less than 500ft. in length should, after at least 24 hours' immersion in sea water, possess an insulation resistance of not less than 1,000 megohms per nautical mile. The conductors were of various sizes from No. 6 to No. 16, and of a single strand of copper, tinned, insulated with the white and black rubber tape, and enclosed in a lead tubing. It was found on wiring that the larger sizes were not flexible enough, and the lead cover, from insufficient thickness, sometimes broke in bending. These two faults have been remedied in later specifications by requiring all large conductors to be stranded, and the lead cover to be at least 0·04in. in thickness. Another advantage in stranded conductors, in addition to greater flexibility, is that all the wires are not apt to be broken together, the breakage of one or two not being fatal. But if a single conductor parts, the circuit is broken and the fault is harder to repair, if indeed it is not entirely concealed by the insulation. Lighting companies were, on account of the increased cost, loath at first to make this change, but the advisability has now been generally recognised. The "Chicago's" plant has been in frequent operation for considerable periods, and has proven satisfactory. No opportunity has been afforded of testing the insulation in actual service at sea, but it is thought that it will fill the requirements. This was the first instance of stipulating a definite insulation resistance in the specifications. It is now a feature of all contracts.

The re-wiring of the "Trenton," likewise by the Edison Company, dates from that time. Contracted for a few months later than the "Chicago," she was finished nearly a year earlier. The specifications were in the main similar, but there was the additional requirement that no conductor should contain a wire of greater diameter than a No. 16 B.W.G., but that the necessary area should be made up of smaller wires, in order to produce flexibility. The "Trenton" being a wooden ship, the bureau was of the opinion that with a good rubber insulation a lead tubing would not be necessary. The requirement was therefore omitted. The wire was manufactured by the India-Rubber and Gutta-Percha Insulating Company, of New York, the same firm that had supplied the Edison Company with the wire for the "Chicago." The mains of the "Trenton" were of two sizes, using seven strands each to No. 16 and No. 18 wire respectively, or, as they are denominated technically, $\frac{7}{16}$ and $\frac{7}{18}$. The branches were a single strand, No. 16. The leads from the dynamo to the switch-board had a core of seven $\frac{7}{16}$ cables twisted together, making in all 49 strands. These conductors were all tinned, parcelled with cotton soaked in a rubber solution and insulated with layers of brown, white, and black rubber successively, and, lastly, a parcelling of rubber tape. The reports received from this ship were in the main satisfactory. Her unfortunate loss at Samoa has made it impossible to know how the insulation would have stood the further test of time.

The "Yorktown" is the last ship installed, and involves all the improvements suggested by previous experience. The contract was sublet by the builders to the Edison Company on specifications drawn by the Naval Inspector. The part relating to the character of the insulation is quoted in full. All conductors, except fixture and portable wires, shall have:—(*a*) A layer of fine braided cotton; (*b*) a layer of rubber, containing no sulphur; (*c*) a layer of vulcanised rubber or Okonite; (*d*) a parcelling of rubber tape; (*e*) a waterproof covering of pure lead not less than $\frac{1}{16}$ of an inch thick. The installation, exclusive of cotton and lead, shall not be less than $\frac{7}{32}$ of an inch thick. It shall, after 24 hours' immersion in sea water have a resistance of not less than 1,000 megohms per nautical mile. . . . A sample of 500ft. of the regular pattern of conductors to be forwarded to a place designated for testing.

The physical characteristics of the insulation shall not change when the conductor complete is raised to the temperature of boiling water nor upon cooling.

Insulation, when complete, with all connections made ready for the use of each and every lamp, the insulation of the entire system of conductors, including the circuits of the dynamo, shall not be less than 1,000 ohms of resistance to every volt of electromotive force of the dynamos. The outer coating of all conductors, all fixtures, junction boxes, switches, receptacles for portables, and all other exterior parts of the system, shall be insulated from the ship. All junction boxes, switches (unless otherwise designated), conductors, joints of conductors, and entrances to fixtures, shall be water-tight). The interior insulating block of junction-boxes and water-tight switches and the bases of other switches and receptacles, also the switch-board, shall be of porcelain, slate or marble.

In making this wire the manufacturers applied first a layer of pure Para rubber over the braided cotton, which was beyond the requirements of the contract, and then the other layers as above enumerated. The conductors were accepted after a number of tests, which were deemed satisfactory. It is too early yet to make predictions, but in two or three months' use there is absolutely no fault to find with the character of the insulation.

The wire supplied the "Pensacola," the "Charleston," and the "Baltimore" is similar to that of the "Yorktown." The dynamo leads are now made in a single cable of the requisite number of strands, instead of a number of seven-stranded cables laid up together, as furnished the "Trenton." On account of the difficulty of braiding over a number of loose strands, a parcelling of cotton is used next the wire. This answers the requirements equally as well. An improvement has been made in the matter of the outer parcelling, which in some cases worked loose in bending, by substituting for it a close braiding of cotton, and soaked in ozokerite.

The flexible conductors for portable lights are of an improved form, suggested by gradual experience, and will be briefly mentioned. The double conductor form seems to be the most desirable when sufficiently flexible, as it is less likely to kink than the separately insulated and twisted strands. It was made at first with an inner stranded conductor, and the strands of the outer one disposed at intervals about it. An extra strand was put in the outer conductor to provide increased cross section and compensate for the extra resistance due to the greater length of the outer-spirals. When these were tried in the "Yorktown" it was found

Digitized by Google

that the outer strands, receiving no mutual support, were apt to be broken by the continual bending at the point of entering the fixture or plug. A new form, now on trial, contains two stranded conductors insulated and laid side by side, with jute fillers to give a rounded cross-section, and a double hemp braiding soaked in ozokerite laid on all over. The resulting wire is flexible, and bids fair to answer well. For use in cabins and officers' quarters, a braiding of floss silk has been employed instead of the hemp. Lately, twilled silk has been substituted, making a smoother and more durable finish. For fixtures that will not admit the regular branch leads, a small stranded conductor is used. The core consists of three No. 25 wires, tinned, insulated with white rubber, vulcanised rubber, and a fine cotton braiding soaked in ozokerite.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *January* 18, 1890.

The Proposed New Board of Electrical Control.—In regard to the underground question in this city, it looks as though it would soon be a case of "The king is dead: long live the king!" The term of office of the present Board of Electrical Control expires by legal limitation next November, and already steps are being taken to provide a successor. Under the present law its duties devolve on the Sinking Fund Commissioners of the city, for what reason I can hardly say, unless it be one derived from a play upon words. The nature of the Board which is to take the place of the old one is now a matter of a great deal of discussion and consultation among the politicians of this city and at Albany, and it is already pretty evident that politics will be mixed up with the next Board much as they were before. The Subway Board Bill, which has been introduced into the State Senate this week, provides that it shall consist of three Commissioners, only one of whom shall necessarily be versed in the science of electricity, the other two being by specific provision not less adept in the science of politics. In other words, the Board is to comprise one Republican, one Democrat, and one electrician. These Commissioners are to be appointed by the Governor by and with the consent of the Senate. They are to hold office for five years, and receive a salary of $8,000 a-year, with travelling expenses. They are to have a chief clerk and a secretary, also appointed by the Governor, and this secretary shall be an executive officer. It does not particularly matter whether he knows anything about electricity or not, but the Bill is careful to stipulate that his politics shall be different from those of the expert. This plan is regarded as the best to ensure the non-partisan character of the Board, and to bring it up to that high level of purity which distinguishes politics generally in this state. One thing noticeable about this Board is that its functions are far more general and comprehensive than those of the old Board. It is to be endowed with powers similar to those of the Railroad Commission, such as administering oaths, investigating accidents, and the like, and is given general supervision over all the telegraph, telephone, electric wires, motor, subway conductor or conduit associations, companies or corporations, and all corporations and associations that in any way "utilise the electric fluid" for the public use or for the purpose of commerce. In other words, the Board is to have the general supervision of the whole electrical business in this state, and it is further charged with the responsibility of seeing that no exclusive privilege or franchise be granted to any corporation, company, or association or person by which a monopoly shall be created or competition shall be prevented. It is possible that this Board may confer some benefits upon the electrical industries of this state, but the measure is evidently one that it will pay all electrical interests to watch closely lest it bring on the whole commonwealth the evils which up to the present time have been the peculiar property of New York City.

The Board of Health and High-Tension Circuits.—An attempt which has just been made in this city to compel the Board of Health to interfere to prevent the operation of high-current circuits has just been defeated. A mandamus was asked for to compel the Board to remove from the streets high-tension wires, but the judge has denied the application on the ground that the busybodies who have interested themselves have no clear legal right to attempt what is asked for. The judge is of opinion that the Act which established the Board of Electrical Control took away from the Board of Health all power in respect to electrical conductors in the city of New York. There is much satisfaction felt generally at the defeat of this little movement, because it is considered that the object in view was not to protect the public health and welfare, but merely to promote commercial ends and to gratify commercial antagonisms. It is to be feared that half the trouble from which we have suffered in New York, and from which, as a result, the electrical interests elsewhere have suffered generally, have arisen from attempts which it would be hard to define in language otherwise than libellous, if we admit the proposition that "the greater the truth the greater the libel."

The Boston Public Lighting Contract.—The situation in Boston at the present time is one of more than local interest. For a long time past the city lighting there has been done by the Boston Electric Light Company, which has received on an average about 50 cents a night for a full 2,000 c.p. arc light. Proposals being invited for new bids, various tenders were made, and the contract has now been taken away from the old company and awarded for the most part to the Suburban Light and Power Company at a rate below 40 cents. per light. The remarkable thing about this is that while the Boston Electric Light Company is an old-established concern that has about a million and a-half dollars invested in its plants and circuits, which ramify all over the city, the Suburban Company have neither plant, nor location, nor circuits; and the result is that, although the new contract represents an apparent saving to the city of about $75,000, there is a good deal of local feeling with regard to the stringing of several hundred miles of new high-tension wires through the streets and over the buildings. The fire underwriters have protested against this, and several real estate owners have joined in opposition. There is more in this controversy, however, than appears on the surface, or in the facts thus far detailed. The root of the whole matter is the competition between the Thomson-Houston and the Westinghouse companies. The old company is friendly to the Thomson-Houston interests, and largely uses the Thomson-Houston apparatus. The new Suburban Company is understood to have Westinghouse interests behind it, and it is said that all the apparatus for the new work has already been ordered from Pittsburgh. Yet another point of interest occurs in connection with the rumour that it is the intention of the Westinghouse Company in carrying out this contract to use its new alternating-current arc lamp, through the introduction of which it claims to secure greater safety for those handling the lamps, and greater economy in the consumption of carbons and the operation of the circuits.

Electric v. Cable Street Railways.—For some time past it has been generally and frankly admitted by street railway men that the horse and the steam engine cannot enter seriously into competition with electricity for the propulsion of street cars. In other words, the competition has narrowed itself down to the cable and the electric motor in the larger cities, the smaller cities being considered at all events the legitimate and proper field for the introduction of electricity as a motive power. The cable interests have been making an ardent and strenuous fight for the maintenance of their grip upon and in the larger centres of population; but it begins to look as if they were losing their hold even there. Thus, for example, the news comes this week from Minneapolis, one of the most beautiful and progressive cities of the country, that the street railway company there has abandoned its intention to equip its system with cables, and now intends to use electric cars, for which it will equip 100 miles of its track throughout the city. What gives the change a greater significance is the fact that the street railway company had already actually bought and accumulated $400,000 worth of cable plant. In view of the advantages to itself and to the public which it plainly sees can be derived from the use of electricity, it has thrown aside all this cable plant, which can now be bought for scrap-iron, and is devoting its energies to the speedy equipment of its system with electricity. The sister city of St. Paul is to follow its example.

Digitized by Google

Instances of this kind are worth volumes of argument, and they are at the same time an adequate confirmation of all the claims the advocates of electricity have maintained for it as the ideal motive power for street-car operation.

Duplex Telephony.—The recent issue of a patent for a method of duplex telephony to Dr. Rosebrough, of Canada, has called forth an article from the pen of Mr. John A. Barrett. This gentleman has had considerable experience in telephony, and especially in the branch relating to long-distance work and duplexing, having until recently occupied the position of electrician to the American Telegraph and Telephone Company, who operate the long distance lines in this country. Notwithstanding the work done on duplex telephony in the past, Mr. Barrett claims—and he, by the way, is also the patentee of one of these devices—that there is still to be offered publicly a reasonable method for multiplying the number of telephone communications upon a single line, *i.e.*, obtaining a true duplex, as in the case of the telegraph. The nature of the telephonic impulses, according to Mr. Barrett, are such that we have not yet been able to devise instruments which would differentiate between two individual messages at the transmitting station, and sift out the same at the receiving station, and hence the enormous difficulty of the problem becomes apparent. Mr. Barrett then points out what has been done in duplex telephony, and cites the "bridge" method, in which two wires are used on a single metallic circuit, and this pair again used as a single line forming a part of another circuit. This forms the principal feature of the patent issued to Mr. Frank Jacob, and in which Mr. Barrett seems to find the fundamental principle of all duplex telephony schemes so far proposed. Thus, according to the present methods, the best that has been accomplished has been the reduction of the number of circuits by one less than the number of messages to be transmitted. Mr. Barrett, however, refers to the fact that by the application of the Jacob patent to the "bridge" method the lines can be used for simultaneous telegraphy without in any way interfering with telephonic transmission. But the reason why this has not been applied in America may be looked for in the fact that the Jacob patent is owned abroad.

Improvements in Quadruplex Telegraphy.—As your readers may be aware, the same difficulty is still experienced in the operation of the quadruplex telegraph, and in seeking to overcome these Mr. Clarence L. Healy, one of our brightest telegraphists, came to the conclusion, on a thorough analysis, that much of the difficulty was due to the high resistance of the local circuits, including that of the battery. Our ordinary quadruplex lines have a line resistance of about 3,000 ohms, but when it has an artificial line attached to it through the differential relays to balance it, the joint resistance offered to the battery current is about 1,500 ohms, and when 300 cells of a gravity battery are connected, as they usually are, by the second side transmitter, the actual potential which reaches the line is that which arrives at the joint lines due to the fall of potential in the battety itself. These 300 battery cells measure 900 ohms or more, and hence the loss in the battery will be in the ratio which this battery resistance bears to the joint resistance of the line, which usually brings it down to one-third in clear weather. It is evident that in bad weather the heavy leakage greatly reduces the percentage of current which is available for the line. Upon the introduction of the dynamo quad in this country, this objection was slightly overcome by the lower artificial battery resistance used between the dynamo and pole changer, being usually two ohms to the volt. But this still caused a large percentage of loss, this high resistance being used in order to prevent the burning of the contact points of the "increasing" transmitter. All these difficulties have been overcome by Mr. Healy, by a new arrangement of the relay and connections. With this relay and local arrangements, briefly, all condensers, induction coils, and extra magnets to "kick" the current through, either winding on the relay, or extra magnets to hold the armature steady at reversals for preventing the mutilation of signals, are done away with. Again, the resistance of two ohms to the volt formerly employed has been similarly replaced by a short fuse wire, which acts admirably, and in fact is a better safeguard against abnormal current than the resistance. Thus, by removing all extraneous resistance, and the avoidance of the retarding effects of induction coils, the practical operation of the system has been very much simplified. Mr. Healy has worked long lines on this system for several months past with excellent success in all weathers.

PARIS NOTES.

(FROM OUR CORRESPONDENT.)

January 27, 1890.

As I mentioned in my last letter, the Commission Technique met on the 15th inst. to consider the proposal of the Conseil Municipal that the members of the Commission should ascertain whether or not all the plant installed at the various central lighting stations in Paris was of French origin. M. Paulard, the originator of this demand, was called upon by the members of the Commission Technique to explain exactly what was wanted by the Conseil Municipal, and his interpretation of the resolution passed at the meeting of this body at the beginning of the year was that the Commission Technique was merely asked to make sure that all the plant bore French marks. A report was subsequently received from the Superintendent of Works to the effect that M. Victor Popp alone employed foreign plant. M. Popp's reason for this delinquency was that, unless he went to the expense of erecting special machinery, it was absolutely impossible to obtain the engines he wanted anywhere but abroad. A striking instance, I think, of the absurdity of this crusade against foreign material.

The Commission Technique, charged with the duty of testing the electricity meters sent in to compete for the prize offered last year by the Conseil Municipal, has terminated its labours, at any rate for the present, and will shortly publish its report. I understand that only half the sum allocated for this purpose by the authorities will be divided among the four or five most meritorious meter makers. The reason for this is not that the meters have given poor results, but that since last May, when the time for entries closed, remarkable improvements have been effected in this direction. It is therefore proposed to inaugurate a fresh competition, and the regulations with regard to it will shortly be made public.

At a meeting of the Association Philotechnique last Friday, M. Laffargue, engineer to the station at the Halles, gave some interesting particulars relating to the erection and working of the municipal electric lighting works. He explained, amongst other things, that the price per kilowatt-hour was fixed at 1fr. 50c., in order not to undersell the various companies who had obtained costly electric lighting concessions from the authorities, although, as a matter of fact, the cost of production was only 70 centimes.

There is considerable talk in electrical circles of a new continuous-current machine of MM. Reignier and Bary, the output of which weight for weight is stated to be ten times as great as that of the best dynamos hitherto constructed, and the cost of which is consideraly less. An official test of the new machine will be made in a day or two, and I hope in my next letter to send you some further particulars.

The electric traction experiments on the Madeleine-Levallois line still continue, and it is rumoured that the tramway company contemplate taking out a licence from the Société Française d'Accumulateurs Electriques. I may mention in this connection that the Compagnie des Tramways Sud have laid a proposal before the authorities that boxes should be placed on their cars in which telegrams may be posted by the inhabitants of the suburbs, these telegrams being given in by the tramway officials at the nearest telegraph office. At Brussels, where the suburbs are as badly off for telegraphic facilities as at Paris, this system has been in successful operation for the last fifteen years.

CORRESPONDENCE.

THE "COUNTER ELECTROMOTIVE FORCE" OF THE VOLTAIC ARC.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: We hear a good deal about a so-called "back electromotive force," or "counter electromotive force," in the voltaic arc, and a great number of experiments have been made to measure what I believe to be a purely imaginary quantity. These measurements all assume that Ohm's law is true for the discharge in the arc; but we know that Ohm's law does not hold for gaseous discharges, and, as far as I can see, we have no

Digitized by Google

independent evidence at present of the existence of any such thing as a counter electromotive force.

Let us see what our measurements can give us. We can ascertain the difference of potential between the carbon poles, or even between any two points in the arc itself. We can also measure the current, and a combination of the two quantities can give us in a given case the relation between the fall of potential and the current: but nothing more than that. We may, if we like, call the ratio of the electromotive force to the current "resistance;" but we have no right to assume that the resistance so defined is independent of the strength of the current or proportional to the length of the arc. Yet this assumption is made wherever the "counter electromotive force" is supposed to be measured.

The measurements are conducted in one of two ways. If E is the difference of potential between the two poles, C the current, and e an assumed counter electromotive force in the arc, we may write $E = C R + e$.

Now, if it be assumed that R follows the same laws as in a solid conductor, we can obtain a second equation by varying the current, leaving the carbon poles as they are, and considering R constant; or we may lengthen the arc and take R to be proportional to the length of the arc. If a second equation is obtained we can calculate e; but, as already pointed out, everything rests on the assumption of the truth of Ohm's law: without that assumption we can gain no information as to e.

Let us go a little further and see what evidence would be necessary to prove a counter electromotive force. If E is the electromotive force between equipotential surfaces of a discharge of any kind, the work done in unit time is E C. If this work appears as heat there is no more to be said about it, but if the actual heat generated is less than E C, some other work must be done, and if that other work is proportional to the current we should have a right, and probably find it convenient, to speak of a counter electromotive force. In an electrolytic cell, for instance, we could in this way determine the electromotive force of polarisation. It seems to me that only when work is done by a current independently of the heat generated by resistance, that we have any reason for speaking of a "counter electromotive force." Such work may possibly be done in the arc. We have in the first place the disintegration of the poles, and have certain chemical actions between the poles and the air. Owing to such work, it may ultimately be found necessary to speak of a counter electromotive force. At present the term seems unnecessary. I believe that a great deal can be found out by a scientific investigation of the voltaic arc, but some of the work which has been done is almost rendered useless by the assumption of the truth of Ohm's law in cases where it does not hold. If investigators were to give their results simply as an experimental relationship between current and electromotive force much more good would be done.—Yours &c.,

ARTHUR SCHUSTER.

THE CLARK STANDARD CELL.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: As the Clark standard cell is now being discussed in the columns of *The Electrician*, I send you the following notes of some recent experiences in the laboratory of these Schools on the change of colour of the mercurous paste referred to by Lord Rayleigh in his article on p. 285.

The paste we used was made from materials supplied by Messrs. Hopkin and Williams—the source, if I remember aright, mentioned by Lord Rayleigh as that from which he obtained the mercurous sulphate used by him.

Soon after mixture the colour of the paste began to change, becoming first yellow, and then, as successive additions of zinc carbonate were made, darker and greener, until after long standing it was quite a dark green. The quantity of zinc carbonate added was very large as the paste kept up a slow effervescence for a very long time.

It was at first supposed that this change of colour was due to the presence of mercuric compounds, together with free acid. Careful tests failed, however, to reveal any perceptible proportion of any mercuric salt, but a very considerable quantity of iron was found to be present in the form of a salt soluble in cold water, probably ferrous sulphate.

By repeated decantations with cold distilled water the iron salt could be washed out of the mercurous sulphate until chemical tests revealed only a very minute residual trace. The water used in the washing, after standing for some time in glass vessels, deposited a yellow incrustation on the sides and bottom of the vessels. The washed salt, when mixed with the zinc sulphate solution, retained its greyish-white colour even after the addition of zinc carbonate in some quantity, although the absence of any effervescence removed the necessity for the addition of the latter. Some paste made from the washed salt has now been in the cells for more than a month and is still as white as at first.

Those cells which were made up with the first and impure paste have, as might have been expected, turned out useless and have been pulled to pieces again. Those made up with the washed salt are now undergoing tests by the students in the laboratory and seem so far to be perfectly satisfactory in their behaviour, the only trouble with them being the greater difficulty of ensuring the complete saturation of the paste.

It would seem from this that the change of colour and deterioration of the paste were due to the presence of the iron impurity in it. But whether the whole effect is to be put down to this cause is not very certain. In washing other portions of the same sample of mercurous sulphate it has been twice noticed, once by myself and once by one of the students, that after the salt had received such a number of decantations that presumably all traces of iron were washed out, on the addition of a fresh bulk of distilled water the salt rapidly and unaccountably assumed a light yellow tint which persisted with further washing. What this is due to I do not yet know: possibly the purity of the wash water may have something to do with it, for if ordinary tap-water is used in the washing the iron is thrown down and the salt quickly changes colour. Those portions of the salt which were thus changed were rejected in making up the cells; the rest, and by far the greater bulk of the washed salt, remained quite unchanged.

H. H. HOFFERT.

"ADVANCES IN MAGNETISM."

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I cannot understand Mr. Esson's objection to the term magnetic resistance, as the analogy appears to me to be very complete, the only difference being that, in almost all substances except iron, $\frac{H}{B}$ is a constant, while under working conditions with nearly all conductors of electricity $\frac{E}{C}$ is a variable. For instance, in the case of an incandescent lamp, $\frac{E}{C}$ is certainly not a constant. Again, it is possible so to proportion an iron wire resistance that, although it only takes about 10 per cent of the power when in series with an arc lamp on a constant volt circuit, yet when the arc is short-circuited, the current only increases by about 20 per cent.

Mr. Esson apparently forgets that, when he is calculating the saturation curve of a dynamo, by far the greater part of the work is to calculate the resistance of the magnetic circuits whose lines do not pass through the armature: these almost all pass through the air, in which case $\frac{H}{B}$ is a constant as far as we know.—Yours, &c.,

H. W. RAVENSHAW.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: May I be permitted to trespass a little on your valuable space by offering a few remarks on the subject of the letter from Mr. Esson, published in your last issue?

The objections put forward in that letter to the term *magnetic resistance* and to an Ohm's law analogy appear to be based upon the supposition that, whereas the property of iron in question *is not* constant for all values of magnetic induction, the resisting property of an electric circuit *is* constant for all values of the current. Even were this a scientific statement of the

Digitized by Google

relative conditions of the two circuits, surely it would not constitute sufficient ground for objecting to the term *resistance* in either case.

But, strictly taken, the conditions are not so essentially different. The Ohm's law analogy is not so wide of the mark as would at first sight appear.

In an incandescent lamp, for instance, the resistance, when there is a large potential difference, is by no means the same as the resistance when there is a small potential difference. So in a magnetic circuit. The magnetic resistance, when there is a large magnetising force, is by no means the same as when the magnetising force is small: both vary. The causes of the variation may be widely different; nevertheless, both vary. We do not quarrel with Ohm's law, we do not object to the term *resistance*, when dealing with electric circuits, on the ground that, because the circuit gets hot, $\frac{E}{C}$ is not a constant. Why, then, should we deny the law, or the term, to the unhappy magnetic circuit, in which the analogous ratio $\frac{H}{B}$ varies also, but happens to vary a little more noticeably?—Yours, &c.

E. T. Carter.

The School of Electrical Engineering, 12, Prince's-street, Hanover-square, January 28, 1890.

THE USE OF THE TERM "ELECTRIC SPLASHES."

TO THE EDITOR OF THE ELECTRICIAN.

Sir: Enclosed I send you a cutting from the *Glasgow Herald* of January 22nd: a most excellent paper generally. The extract shows well the danger of using unmeaning catch words, like "Electric Splashes," and unmeaning action suggestive of "throwing electricity."—Yours, &c., A Correspondent.

January 23, 1890.

The following are some passages from the *Glasgow Herald* article to which our correspondent alludes:—

Some years ago a controversy raged somewhat hotly with regard to the question as to the nature of electricity, whether it was a fluid in itself or merely a peculiar condition assumed by matter. . . . Prof. S. P. Thompson has just exhibited at the Physical Society some experiments which would furnish powerful arguments in favour of the fluid theory. He made use of the interesting Lichtenberg figures formerly employed in the lecture room, but not much known now. . . Prof. Thompson modifies the experiment by holding the Leyden jar firmly in his hand, and, as it were, throwing electricity from the charged knob at the disc, instead of rubbing the surface with it as is usually done. After doing this several times in front of different parts of the plate he again peppers it with the dust, and the result is seen in the presence of figures which do not at all resemble those of Lichtenberg, but rather look like the splashes from a heavily charged paint brush loaded with colour thrown on to the surface in the manner employed by bookbinders when producing the well-known mottled edges of books, or by decorators in imitating granite. The experiment is a novel one, and its exhibition created much interest on the part of the audience.

[We are afraid no amount of care in word choosing would prevent the non-technical press from making absurd mistakes.—Ed. *E.*]

UNDERGROUND MAINS.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: I have read with interest the article on "Underground Mains" in last week's issue. There is, however, one clause which might lead to unnecessary thinking and misconception. Near the bottom of page 286, the author speaks as follows:—"The wires being all straight and separate and *not* in the form of a *cable*." In his next clause, which I also quote, he says: "When wires of a greater length are required to be drawn in than can be done at once, they are drawn through a certain distance and then coiled up; the coil is next turned over and the *cable* drawn through a further section, and coiled up again." In his first clause he says the wires are not made up in the form of a cable, whereas in the following clause he speaks of the wires being drawn through in terms of a *cable*. The word cable is *not* in terms with the sense of the sentence, as he uses the word "*they*" are drawn through, which distinctly points out that the wires are drawn through; and as the author is describing the Post Office system of underground mains, a part of which is the wires being all straight and *not* in the *form* of a *cable*, it is rather misleading and contradictory when in the next clause he says the "*cable*" is drawn through. It will be also noticed that he frequently speaks of "wires" in these clauses, and not "cable." I think that the word "cable" in the last clause should be replaced by "wires." The sentence would then read, "the coil is next turned over and the *wires* drawn through a further section, and coiled up again."—Yours, &c.

Gerald St. John Day.

ELECTRO-MAGNETIC APPLIANCE FOR TURNING ON GAS-LIGHT.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: Would any of your numerous readers kindly inform me as to the best appliance for above, with gas burner best adapted for same? Four lights; line wire 60ft.: how many No. 1 Leclanché cells would be required? Would one line wire do, using earth for return current?—Yours, &c.,

John F. Neave.

2, Catherine-street, Dundee, January 21, 1890.

SIMPLE WIRING EQUATIONS.

Many convenient sets of tables and rules have been issued during the last year or two for the purpose of facilitating wiring calculations, and the two simple equation rules, with table, given below are, we think, likely to prove of use. They are due to Mr. J. Sayers, of Derby.

Let l = length in feet of wire (positive and negative),
c = average current strength to be carried,
e = loss of E.M.F. in wire, which in equation (1) would be decided upon beforehand, and in equation (2) the quantity to be ascertained.

Then, if the size of cable required for a certain current and length is what is wanted, it is readily obtained by

$$\frac{l \times c}{e} = x \quad . \quad . \quad . \quad . \quad . \quad . \quad (1).$$

If the loss of E.M.F. in a cable already fixed or planned of certain length and current strength is required, it is given by

$$\frac{l \times c}{x} = e \quad . \quad . \quad . \quad . \quad . \quad . \quad (2).$$

The values of (x) for the best-known sizes of wire and cables are given below; they really represent the feet per ohm for the particular cable:—

Values of (x).

B.W.G. No.	B.W.G. No.	B.W.G. No.
18 = 215	7/15 = 3458	19/15 = 9385
16 = 393	7/14 = 4702	19/14 = 13095
7/20 = 870	19/20 = 2362	37/15 = 18276
7/19 = 1299	19/19 = 3527	37/14 = 24882
7/18 = 1612	19/18 = 4374	37/13 = 31826
7/17 = 2181	19/17 = 5919	37/12 = 41905
7/16 = 2750	19/16 = 7462	

For example:—Case 1: A corridor 100ft. long, average current 15 amperes: what cable is required to have loss of ·5 volt? Answer is (length = (100 × 2))—

$$\frac{(100 \times 2) \times 15}{\cdot 5} = 6000,$$

and nearest cable corresponding to 6000 in table is 19/17—cable required.

Case 2: A cable 200yds. long, positive and negative together, made of 19/18, carries average current of 7 amperes: what is loss from end to end? Answer: (19/18 = 4374 in table)—

$$\left(\frac{600 \times 7}{4374}\right) = \cdot 96 \text{ volt.}$$

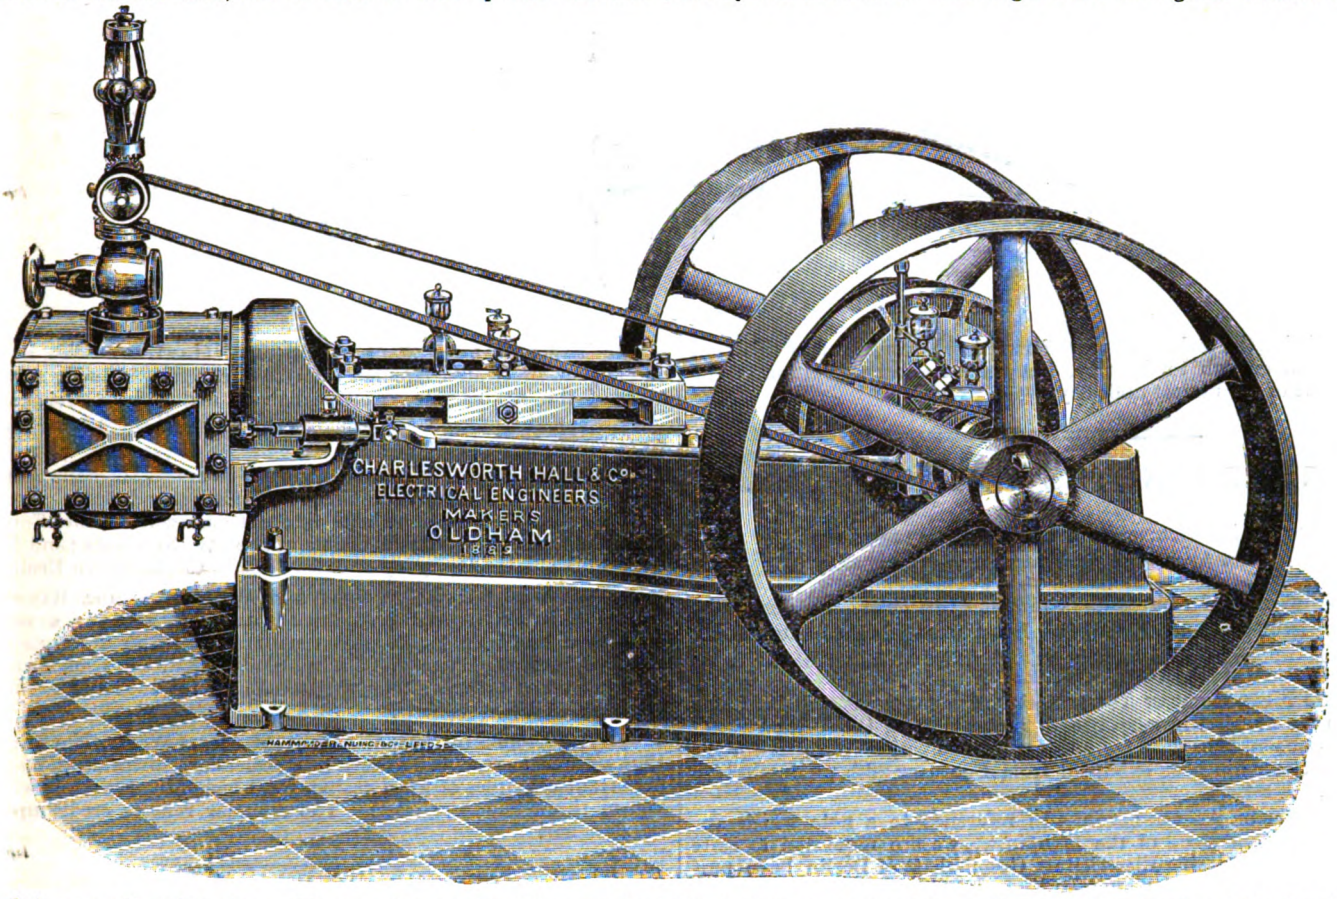
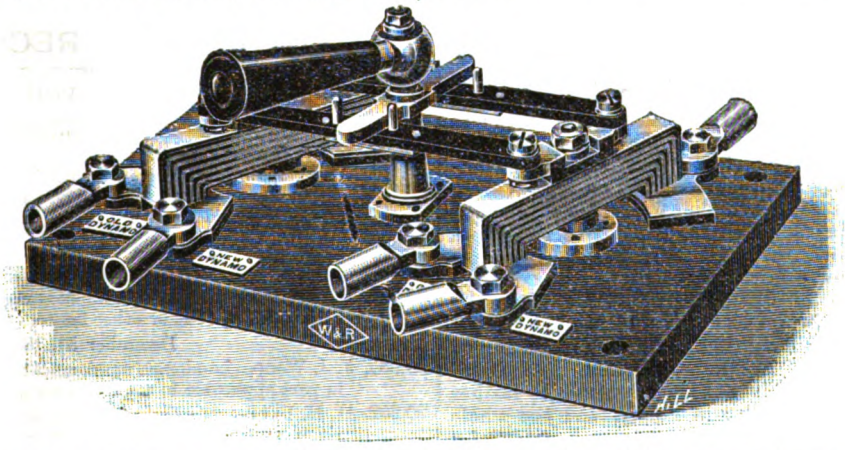
CHARLESWORTH, HALL, AND CO.'S ELECTRIC LIGHT ENGINES.

Our engraving shows a horizontal engine of a type lately brought out by Messrs. Charlesworth, Hall, and Co., and intended principally for driving electric light machinery. These engines are of massive construction, and having very stiff shafts and large bearings are capable of making long continuous runs. The cylinders have piston valves, lapped and ground, and in order to get a good opening to steam they are double ported. The crankshafts are of forged steel, and, as mentioned above, are exceptionally stiff. The crank webs are circular and have cast-iron balancing discs shrunk on to them. The slides are of the four-bar type, the bottom slides being planed on the bed itself, and in order to take up wear the slide block has an adjustable shoe. Wear on top can be taken up by letting down the top bars. The slide surfaces are very large, and so adjustment will very seldom be necessary. The piston rod is of hard steel, fixed by a cone and nut into the piston and cottered into the slide block. The valve rod is fixed permanently into the valve and has an adjustable joint into the guide, so that the valve can be adjusted without removing the valve chest covers. The connecting rod is adjustable at both ends. Pickering governors are fitted on the valve chest inlet. Automatic or hand expansion gear can, however, be fitted, if preferred. Careful attention has been paid to the question of lubrication, so that all parts can be lubricated whilst running. In order to balance strain on the crankshaft two flywheels are used. The engines are throughout finished in the best manner possible, and are giving much satisfaction in regular work.



THE WOODHOUSE AND RAWSON DOUBLE-POLE TWO-WAY SWITCH.

Our illustration shows a new form of switch, which is likely to find favour with those who advocate the double-pole arrangement of switches, and its construction contains one or two interesting novelties. It will be seen that the brushes are built up in a somewhat different way to the well-known multiple brush hitherto employed in switches of Woodhouse and Rawson: they are given a still greater individuality of movement by separating each part from the adjacent one with a washer in the centre, and for simplicity of construction they are made with square corners in place of round.



The cross-bars which connect the two brushes are of vulcanite, which possesses sufficient strength and the necessary elasticity and insulating properties. The method of attachment for the cables is the very convenient movable socket form into which the cable is sweated. The switch appears to be well designed for a class of work which is in common demand.

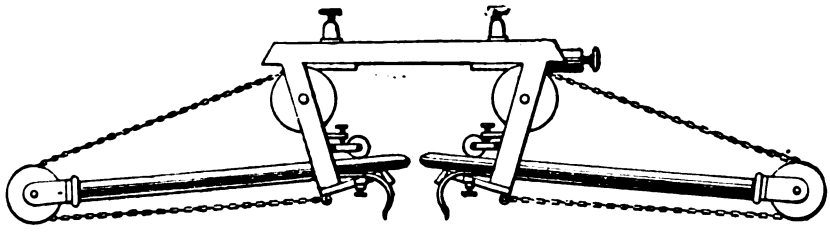
THE SOLIGNAC ARC LAMP.*

Among the many curious devices for bringing arc lamp carbons together, independently of the resistance of the arc, that proposed by M. Solignac is conspicuous. The apparatus is shown in the accompanying figure. The carbons are moved by an arrangement of drums and chains. A small glass rod is fixed underneath each carbon along its entire length. The end of each carbon is gripped between a roller and a support. To start the apparatus, the carbons are made to touch by turning a screw, and are then pulled apart, striking the arc. As the carbons are consumed the glass rods become soft, and bend over as shown in the figure, thus permitting the carbons to move forward. An apparatus of this kind is simple enough to describe, but the practical realisation of the same is of the utmost difficulty.



The Solignac Arc Lamp.

* Translated from M. Hippolyte Fontaine's "Éclairage à l'Électricité," by kind permission of the Author.

TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning.*]

We would refer our readers to some particulars relating to the 1890 issue of *The Electrician* ELECTRICAL TRADES' DIRECTORY and HANDBOOK, given on pages xii. and xiii. of Advertisements.

THE METROPOLITAN TOWER.—An announcement will be found on page xv. that in response to requests from the United States and Canada, the time for sending in competitive designs for the great tower has been extended from February 28th to March 14th next.

THE TUDOR ACCUMULATOR.—In reference to a note which appeared in our issue of the 17th inst., we are requested to state that the Allgemeine Electricitats Gesellschaft of Berlin have purchased the right of manufacturing the Tudor Accumulator, but have not purchased the Tudor Accumulator manufactory at Hagen, as incorrectly reported.

THE AMALGAMATED UNION OF ELECTRICAL OPERATIVES.—A notice is issued that the adjourned meeting of this Union, of which Mr. R. Steadman is secretary *pro tem.*, will be held at the Paul's Head, Paul-street, Finsbury, on Saturday, February 1st, at 7.30 p.m., "to further proceed with the rules and elect officers for the year."

MESSRS. J. G. STATTER AND CO. (LIMITED).—This firm write us as follows:—"Of the principal improvements in our manufactures made during the year 1889, the following may be noticed. For large machines for low and moderate tension, we have adopted the single circuit field-magnet, made entirely of wrought iron, machined all over. These machines are provided with drum armatures and are ventilated, and we are so satisfied with the success of these machines that we are constructing a series to correspond to the outputs for larger sizes. For constant-current and on high-tension machines we have adopted the double circuit field-magnet, and the sectional ring armature (Joel's patent). The above two types of machine will be our stock pattern. Our patent constant-current machines have found a fair number of buyers. During the past year we have constructed a pair of our D.R. size (37½ units each), and we believe that the great utility of constant-current machines is gradually becoming recognised. Our combined engine and dynamo, consisting of one of our improved high-speed open-type engines, belted to one of our standard-type dynamos by leather link belt and tightened in by a setting-in pulley, and the whole mounted on a box bed-plate of cast iron, has been successfully introduced by us during the past year, and many have been sold and are in successful operation. Our energies have been devoted during the past year to the perfection of machinery for the transmission of power, and for telpherage and light railways. We have constructed 11 electric locomotives for telpher electric railways, some of these having a tractive force of 1,500lb. on the draw-bar. In alternating machinery, we have made considerable improvements. The transformers used for the lighting of Chelmsford by Messrs. Crompton and Co. (Limited) are Statter's patent, and were made by us. Messrs. Crompton have been supplied with some additional ones for their installation at the Barry Docks. We have also taken up the manufacture of alternators for central station lighting, and we have now in hand several for an important central station." This firm has now been incorporated with the United Electrical Engineering Company, under the title of "The Electrical Engineering Corporation (Limited)."

THE ELECTRICAL ACCESSORIES COMPANY (LIMITED).—We have received an illustrated circular from this company showing specimens of the Atkins patent universal shade and globe carrier, ceiling roses, and fancy nurls. Prices are given of all these articles in the circular under notice.

TRADE CALENDAR.—We have received from the Magnolia Anti-Friction Metal Company of Great Britain a handsomely-got-up calendar for 1890, upon which views are shown of the Forth Bridge; the Eiffel Tower; the Statue of Liberty, New York; and the large works of the Company situated close to the Brooklyn Bridge.

———We have also received from Woodhouse and Rawson United (Limited) a useful illustrated calendar, showing a very large number of their well-known manufactures with descriptions attached, and we also have to acknowledge from the same firm a useful celluloid paper knife, giving a calendar for 1890 and French and English measurements.

———From Mr. Samuel Elliott, of Albert Works, Newbury, Berks, we have received a very neat calendar, illustrating many important examples of wood casing, for which Mr. Elliott is well-known throughout the trade. The calendar reflects credit upon the designer.

COMPANIES' MEETINGS & REPORTS,

The Australasian Electric Light, Power, and Storage Company (Limited).

An extraordinary general meeting of the shareholders of this Company was held yesterday at the offices, 39, Coleman-street, Mr. B. H. Van Tromp presiding.

[The objects for which this meeting was called will be found set out on page 333.]

The SECRETARY (Mr. J. H. Duncan) having read the notice convening the meeting,

The CHAIRMAN said that it would be within the recollection of the shareholders that when they last met he told them of the possibility of there being some little difficulty in getting actual legal possession of the whole of the patents, and that it might be the case that, for the present at all events, there would be a small reduction made in the purchase-money. When he told them that the patents were altogether ninety-seven in number, and that they related to India, Tasmania, New Zealand, Natal, the Cape of Good Hope, Victoria, and all the Australian Colonies, it might be easily imagined that, having regard to the scattered countries to which those patents referred, there had been considerable difficulty in getting, as it were, immediate and actual physical possession of the letters patent and the necessary and proper assignments. The Electrical Engineering Com

Digitized by Google

pany had, he thought, very properly called upon them to show, in the strictest possible way, their full title to those patents, and he was glad to be able to say that they had completed an assignment to that Company of the greater portion of them. They had executed—or would execute in the course of that day—a deed assigning to the Electrical Engineering Company 73 of those patents, representing a value of £23,500 out of the £30,000, which, as they would remember, was the total consideration to be paid for the whole of the patents. It was really £31,000, but that, as they were probably aware, was to include the whole of the expenses of the winding up. That being so, the Board thought it better, in the interests of the Company, rather than wait until they produced proof of their title to the whole of the patents, to go as far as they could, and to complete an agreement with the Brush Company to the extent he had indicated, having regard to the fact that they had the fullest belief that, with respect to nearly the whole of the patents, they would be able, and in a very short time, to show a very good and indefeasible title to them. It was not at present proposed to issue the shares in the Company representing the £23,500, but they would obtain an undertaking from the Brush Company to issue the shares as and when required. It was not proposed that the shares should be issued at once, for the reason he had stated, that he believed they would get nearly the whole of the £30,000, and it that case it would be better to issue the shares at once rather than in driblets. He need not say how difficult it would be in a large body of shareholders to apportion the remaining 3,000 or 4,000 shares, but he hoped that in the course of a month or six weeks they would receive those shares and become proprietors in a new and prosperous undertaking. With regard to the winding up, by the agreement of October last the right was reserved by the Brush Company to purchase the remaining assets at the upset price of £15,000, and they were to exercise that option on or before February 1st. That day was fast approaching, and it had been intimated to that Company that the Board desired them to say whether or not it was their intention to accept the assets undisposed of at £15,000. His own impression was that they would not do so, but that they would prefer the Australasian Company themselves, as a matter of convenience, to realise their own estate. They knew naturally where it was, what it consisted of, and how best to realise it. He might mention the circumstance as showing that the Brush Company desired to bring matters to an issue as soon as possible, that it was at their request that the present meeting had been called, so as to close up the Company and hand over the assets as arranged. And this was the only course open to them. Under the law the Company remained alive, as it were, until such time as they had completely wound up their affairs. With these few observations he would now beg to formally move :

"*That this Company be wound up voluntarily.*"

"*That John Henry Hill Duncan, and Benjamin Humphries Van Tromp be and they are hereby appointed Liquidators of the said Company.*"

"*That the said Liquidators be and they are hereby directed to carry into effect the Agreement entered into between this Company and the Brush Electrical Engineering Company (Limited), dated October 23, 1889, so far as the same remains to be carried out, and either with or without modification.*"

He might add that, though there were very few shareholders at the meeting, in point of fact the Directors had received proxies representing nearly a holding of £60,000, assenting to the object for which the meeting had been convened. He did not think they had received an intimation of dissent from any one shareholder.

Mr. ROWAN seconded the resolutions, which were adopted unanimously and without discussion.

The CHAIRMAN further added that Mr. Sellon, on behalf of the Brush Company, had recently been in Australia, and had come back in the belief that there was a great future for the electric light in that country. About two years ago, having that fact in view, a proposal was made by the Board for increasing the capital of the Company, and circulars were sent out to the shareholders inviting subscriptions, but at that juncture the Directors did not meet with that support which they expected, and they were obliged to make the best terms they possibly could to realise the Company's property.

A vote of thanks to the Chairman terminated the proceedings.

Anglo-American Telegraph Company (Limited).

The following is the report of the Directors of this Company to be presented at the ordinary general half-yearly meeting of the proprietors, to be held at Winchester House, Old Broad-street, London, E.C., on Friday, the 31st inst., at 2 o'clock :—

1. The total receipts from July 1 to December 31, 1889, including the estimated balance of £2,465. 1s. brought forward from the last account, are estimated at £157,109. 4s. 11d. This amount, however, is subject to revision, dependent upon the result of the law-suit still pending between this Company and the Paris and New York Telegraph Company. The traffic receipts show an increase of £23,839, as compared with the corresponding period of last year, and this increase would have been considerably larger had it not been for the interruptions which have occurred during the past year to the cables of the associated companies. For some weeks during the half-year under review the whole of the traffic was thrown on to the cables of this Company, and, in consequence, its volume was sensibly diminished.

2. The total expenses of the half-year, including repair of cables, &c., as shown by the revenue account, amount to £58,611. 12s. 3d.

3. Interim dividends of 12s. 6d. per cent. on the ordinary stock, and 25s. per cent. on the Preferred stock, were paid on November 1st last, absorbing £43,750, leaving an estimated balance of £54,747. 12s. 8d., out of which the Directors recommend the proprietors to declare final dividends of 15s. per cent. on the ordinary stock, and £1. 10s. per cent. on the Preferred stock, amounting to £52,500, making a total distribution for the year ended December 31, 1889, of £2. 15s. per cent. on the ordinary stock, and £5. 10s. per cent. on the Preferred stock, leaving an estimated balance of £2,247. 12s. 8d. to be carried forward to the next account.

4. The Company's repairing s.s. "Minia" has been engaged during the past half-year in the repair of the Brest-St. Pierre cable, broken on July 17th, communication having been restored on September 5, 1889. When at some distance from Falmouth she unfortunately came into collision with an Italian barque, the "Caterina Capurro," of Genoa, during a dense fog. Considerable injury was sustained by both vessels, but as the "Minia" was insured, no direct loss was sustained by the Company beyond the loss of time involved in refitting and the consequent necessity of employing the Telegraph Construction and Maintenance Company's s.s. "Britannia" to repair another fault which appeared in the Brest-St. Pierre cable on November 14th at 150 miles from St. Pierre. The "Britannia," after picking up both ends of the cable, and renewing 35 miles by laying in new cable, was driven by stress of weather and shortness of coal to temporarily abandon the work and return to port. In the meantime the "Minia" had arrived at St. John's, Newfoundland, and, being fully equipped, at once proceeded to the spot, and successfully completed the repair on December 12th.

5. The whole of the Company's system of cables and land lines is now in good working order.

6. The litigation between the Anglo-American Telegraph Company and the Paris and New York Telegraph Company is still pending, the Appeal to the Conseil d'Etat not having yet been heard.

7. The Directors are pleased to be able to report that the Western Union Telegraph Company, lessees of the American Telegraph and Cable Company, have extended their main cables from the landing place at Canso, Nova Scotia, by new cables direct to New York City. This extension will not only greatly expedite the traffic all the year round, to the joint benefit of

PATENT
SILICIUM BRONZE AND SILICIUM COPPER WIRE.
The best for overhead Telephone and Telegraph Lines,
AND ALL ELECTRICAL PURPOSES.

Digitized by Google

the associated companies, but will neutralise the effect of storms upon the land wires, which during the winter occasionally caused delay in the transmission of messages.

8. As a result of adding to the carrying capacity of the Western Union Company's system by the above extension of their cables, they have been enabled to transfer to this Company the use of two wires between North Sydney and New York City, and, under agreement between the two Companies, this Company will shortly open an office at No. 8, Broad-street, New York, and thus establish direct and complete telegraphic communication between New York and London by their own lines. By the opening of this new office and the extensions referred to, the Company will be placed "in touch" with the New York public, and the Directors hope that the more certain and accelerated service now provided will increase the traffic upon the cables of all the associated companies.

9. In accordance with the Articles of Association, two Directors of the Company, the Right Honourable Viscount Monck and Samuel Barber, Esq., retire at this meeting, and being eligible, offer themselves for re-election. The Directors greatly regret the loss by death of their colleague Sir Daniel Gooch, Bart., who has been connected with the Company from its inception, and assisted in the laying of the original cables. Mr. Charles Burt, till now solicitor to the Company, having retired from professional business, has been elected to fill the vacancy during the remainder of Sir Daniel Gooch's term of office. The Directors consider that Mr. Burt's intimate knowledge of the Company's affairs from the commencement of the undertaking will render his services exceptionally valuable.

10. Mr. Joshua Dean and Mr. Francis Glass, the Auditors, also retire. Mr. Dean offers himself for re-election, but Mr. Glass, on account of failing health, does not desire re-election, so that the appointment of a new Auditor will be necessary

NEW COMPANIES REGISTERED.

THE BANGWAKETSI CONCESSIONS SYNDICATE (LIMITED).—Registered by R. Jordan, 120, Chancery-lane, E.C., with a capital of £30,000, in £1 shares, with power to increase or reduce the same, and to issue any of the shares of the syndicate for the time being, either at par or at a premium. Object: to adopt and make binding upon the syndicate, and to carry into effect an existing proprietorship between Ferrar Fenton of the first part, Reginald Fenton of the second part, James Potter Ablett of the third part, and Charles James Riley of the fourth part; to carry on and develop certain concessions or leases for 99 years, for the selection of trading stations, and for the construction of railways, telegraphs and telephones, and for the production and selling electric light, and the erection of factories and other industrial works upon the said properties, and dealing in the products thereof, granted by the paramount Chief Bathoen in the Bangwaketsi country, and to obtain other concessions as well as leases, leases and lands for trading, and all other commercial purposes, in the neighbouring territories; to carry on the business of a mining, smelting, trading, and metallurgical syndicate, in all its branches, in South Africa, Great Britain, and elsewhere. The number of directors shall not be less than three nor more than nine, and the first shall be appointed by a majority of the subscribers to the memorandum of association. The directors' remuneration shall be at the rate of £100 per annum, with an additional £10 per annum to the chairman.

MILLS CYCLE COMPANY (LIMITED).—This Company was registered on the 18th inst. with a capital of £10,000, in £5 shares, to carry on the business of cycle manufacturers, and to carry out an unregistered agreement of 8th inst. between George Pilkington Mills and Nathaniel Hemming; also to trade as electricians, iron and brass founders, and engineers. Solicitors: Messrs. Burgess and Cosens, 9, Finsbury-circus.

NORWICH ELECTRICITY SUPPLY COMPANY.—Objects: To carry on at Norwich and elsewhere the business of an electricity company in all its branches. Capital, £50,000 in £10 shares. Borrowing powers not to exceed nominal amount of capital. Registered January 25th by George B. Kennett, solicitor, Norwich.

A NEW COMPANY.—The formation of a limited company, with a capital of 30,000,000 marks, for the construction of hydraulic and electric power distribution works in German towns (Popps' patent), is announced from Berlin.

CITY NOTES, &c.

AUSTRALASIAN ELECTRIC LIGHT, POWER, AND STORAGE COMPANY (LIMITED).—The following circular has been issued to the shareholders of this Company:—"I beg to give you notice that an extraordinary general meeting of the shareholders of the above Company will be held at the registered offices of the Company, situate at 39, Coleman-street, in the City of London, on Thursday, January 30th next, at 12 o'clock noon, at which it will be proposed to pass the following resolutions, viz.:—1. That this Company be wound up voluntarily. 2. That John Henry Hill Duncan, and Benjamin Humphries Van Tromp be, and they are hereby appointed liquidators of the said Company. 3. That the said liquidators be and they are hereby directed to carry into effect the agreement entered into between this Company and the Brush Electrical Engineering Company, Limited, dated October 23, 1889, so far as the same remains to be carried out, and either with or without modification.—By order of the Board, J. H. Duncan, F.C.A., Secretary." The circular further states that the assignment of the patents and other assets disposed of to the Brush Electrical Engineering Company (Limited) is practically completed, and it is expected that it will be absolutely so before the date of the meeting hereby called, at which the Directors will no doubt be able to give final information as to the state of matters. A report of the Proceedings at the above meeting will be found on page 331.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended January 24th amounted to £5,354.

CONTINENTAL INDIA RUBBER WORKS.—The Continental India Rubber Works in Hanover has announced a dividend of 2fr. per cent. for 1889.

EDISON-SWAN UNITED ELECTRIC LIGHT COMPANY.—This Company intend to pay an *ad interim* dividend at the rate of 7 per cent. per annum upon the "A" shares, to be distributed in accordance with the Articles of Association. It is intended to issue the dividend warrants on February 20th.

MORGAN'S AUTOMATIC ELECTRIC SIGNAL SYSTEM SYNDICATE.—Objects: To acquire, develop, and turn to account rights of any description connected with Morgan's Automatic Electric Signal System, and to carry on any manufacturing business likely to effectuate such objects, adopting therefor an agreement dated January 24, 1890, made with Otto Friederici, the particulars of which are not specified in the Articles of Association. Capital, £5,000, in £100 shares. Registered, January 27th, by Hindson, Miller, and Vernon, solicitors, 8 and 10, Moorgate-street.

SCHANSCHIEFF ELECTRIC SYNDICATE.—On Wednesday last week a meeting of the shareholders of the Schanschieff Electric Battery Syndicate (Limited) was held at the offices of the Company, 44, Basinghall-street. Representatives of the press were not admitted.

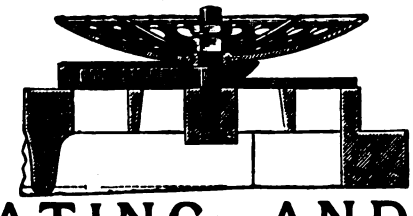
THE AMERICAN BELL TELEPHONE COMPANY.—A correspondent writes:—"Net earnings in 1889 applicable to dividends were not far short of $2,700,000, as against $2,436,464 in 1888, $2,237,608 in 1887, $1,973,351 in 1886, and $1,809,996 in 1885. This shows an average rate of increase from year to year for the last three years of 10½ per cent. Bell's dividends are $18 per annum, and the stock now sells at 200, showing 9 per cent. on the investment. The Bell's patent will expire by limitation shortly, but the Company has possession of the field, and is apparently established on a sound basis."

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended January 24th, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited), were £4,044.

WINFIELDS (LIMITED).—A petition for the reduction of the capital of this Company came before Mr. Justice North in the Chancery Division on Saturday last. It was proposed to reduce the capital, now standing at £160,000 (divided into 24,000 Preference shares of £5 each, and 8,000 ordinary shares of £5), by the sum of £49,634; and, further, to reduce the nominal amount of the unissued Preference shares from £5 to £3 a share. It was stated that no dividend had been paid since November, 1887, and that each year the losses had been carried to a profit and loss account, the accumulated deficit amounting to £7,859. The stock, plant, electric installation and machinery had become depreciated, amongst other causes, from the fall in the price of copper. His lordship granted the petition.

NEW VALVE

No Rubber, Percha, or Leather.



One-half the price of Rubber or Metal.

FOR CIRCULATING AND AIR PUMPS.

Unaffected by any Lubricating Oils. Does not Expand in diameter. Feed Water may be worked at any temperature Suitable for any shaped guards. Only one quality manufactured.

"12, John-street, Sunderland, 28th Sept. 1885.

"DEAR SIRS,—In reply to your letter of the 25th inst., the Valves I got from you have done their work well, and ARE AN UNQUALIFIED SUCCESS. I will continue to get them from you as required.—Yours faithfully, JAMES WESTOLL."

For further Testimony and Prices, apply to MOSSES & MITCHELL, 68-71, Chiswell Street, London.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 612.—Vol. XXIV. FRIDAY, FEBRUARY 7, 1890. Price Fourpence.

NOTES.

Some not unnatural surprise has been expressed in various quarters that the Electrical Trades Committee of the London Chamber of Commerce took no action at its meeting last week in respect to the "blocking orders" which are being pressed forward by local authorities owning gas works, with the object of excluding electric lighting undertakers from outside. The matter was, however, privately discussed prior to the meeting, and there being a general consensus of opinion that for the present, at any rate, it would be sufficient to keep a sharp watch on the local authorities in question, the subject was allowed to drop. The large amount of work now in hand and in prospect, no doubt greatly contributed to the adoption of this attitude of masterly inactivity. We would, however, point out that the danger to be apprehended is not so much that gas-owning local authorities will take no steps whatever to exercise their statutory powers, but that they will pursue the far more insidious policy of doing the work in a perfunctory manner. Such tactics, if skilfully worked, would enable them to say to the Board of Trade, on the one hand, "We are, you see, fulfilling our obligations, but there is really no demand for the light;" and to the ratepayers, on the other hand, "We would willingly extend our operations, but electric lighting does not pay"—a mode of obstruction which would probably prove highly effective.

We may mention in this connection that in consequence of the overworked state of the staff, it is said to be the intention of the Board of Trade to proceed only with unopposed Orders this Session.

In view of the present rapid increase in house lighting, and the consequent need for satisfactory meters, the report of Mr. Kapp on the performance of the Aron meter is most opportune. A reason often advanced by parish authorities against the adoption of the electric light is the assumed absence of any commercially reliable meter. It will be seen from the report in our columns that this objection is quite groundless. The Aron meter has been tested for both direct and alternating currents, varying in value from the largest to the smallest intended to be used with it. Mr. Kapp finds that if the meter is properly adjusted when it is installed, the maximum possible error is one-half per cent. with direct currents, and one and a-quarter per cent. with alternate currents. In practice the error would be much less. The Aron meter seems, therefore, more correct than a gas meter, and its accuracy more than sufficient for practical purposes.

Prof. Fitzgerald and F. T. Trouton, in letters communicated to our contemporary *Nature*, have referred to experiments showing that multiple resonance has already been observed in connection with electric oscillations. It seems that some of Hertz's earlier experiments were more especially concerned with these very effects. It has been found by Trouton that the distance between the nodes alters when a change is made in the dimensions either of the resonator or of the vibrator. In the experiments of Sarasin and Rive, which we published last week, the wave length was found to be altered only when the resonator was changed. If the resonator is such that it will, when acting as a radiator, give out waves of several periods, it will, when acting as a resonator, respond to any wave whose period is one of these. It is desirable to obtain a resonator responding only to waves of one period, and in this Sarasin and Rive appear to have succeeded, since only one wave length was noticed with each resonator. Trouton points out that Hertz has always chosen his receiver so as to give the longest spark, and has thus ensured resonance with the most prominent waves of the oscillator, the frequency of these being presumably given by the ordinary theory.

From the same source we learn that if a high-resistance galvanometer be connected with two sides of the resonator a deflection is obtained whenever a spark passes. This method of detection is not only much more sensitive than the optical one, but has the great advantage that the observing instruments can be placed at a great distance from the receiver. Prof. Fitzgerald states that the method has yielded satisfactory results when the wave length of the oscillations investigated has been only 0·6 metre.

We publish this week a full abstract of the paper on "Galvanometers" by Messrs. Ayrton, Mather, and Sumpner, which was read at the Physical Society on January 17th. The Paper covers a great deal of ground and represents the results of an immense amount of careful and patient work. The very full investigation of the different factors which together determine the sensitiveness of a galvanometer should be of great value to makers of these instruments. Some of the improvements

Digitized by Google

suggested are of an extremely fundamental character, and we would remind our readers that the Paper is to be discussed at the meeting of the Physical Society this afternoon, and urge such of them as are interested in the manufacture of galvanometers, and who may have suggestions to make or criticisms to offer, to attend the meeting and take part in the discussion. The fact that galvanometers of the d'Arsonval type may be constructed to give deflections proportional to the current strength over a considerable range is of great importance, especially in view of the conclusion arrived at by the authors, that a modification of the d'Arsonval type of galvanometer is the one from which the highest degree of sensitiveness is to be expected. Instrument makers would do well to lay to heart the remarks on the insulation of galvanometer coils and terminals.

SOME of the earlier of the many valuable researches of Dr. GORE were concerned with the molecular changes occurring when iron is heated or cooled. These investigations, as Dr. GORE points out in our columns this week, have formed the basis of subsequent experiments. They were probably not alluded to in Dr. HOPKINSON'S address because the aim of the President was to summarise the most important facts about magnetism, and to emphasise certain of them, rather than to judge the work of the various experimenters to whom these facts are due.

M. ALPHONSE BERGET has recently communicated to the *Comptes Rendus* the results of some experiments to determine the relative conductivities of various metals for heat and electricity. The thermal conductivity was found by comparison with that of mercury which had been previously measured. The electric conductivity was determined by means of Sir WILLIAM THOMSON'S double bridge. The same specimens of metal were used for the two measurements, which were all made at temperatures varying from 0° to 30°. It was found that the numbers representing the ratio of the electric and thermal conductivities of the metals copper, zinc, brass, iron, tin, lead, antimony, and mercury are respectively 1·6, 1·7, 1·7, 1·7, 1·8, 1·6, 1·7, and 1·8. The two conductivities may, therefore, for most purposes be regarded as proportional, although the ratio is not rigorously constant. Experiments were also made to determine the influence of temperature on the conducting powers of the metal mercury. It was found that between 0° and 300° C. the percentage decrease of conductivity per degree is 0·046 for the thermal, and 0·085 for the electric conductivity.

THE formula of M. GÉRARD for calculating the candle-power of arc lamps fed with continuous currents seems sufficiently accurate for practical purposes. This formula states that the mean spherical luminous intensity is equal to half the horizontal intensity, together with one-quarter of the maximum intensity. According to the *Centralblatt für Electrotechnik*, experiments on several different lamps have shown that M. GÉRARD'S formula gives the candle-power within about 5 per cent.

PROF. LANGLEY has recently been investigating, by means of his bolometer, the comparative radiation of the sun and the electric arc in different parts of the spectrum. The result given is that the solar radiation in the orange and red is nearly ten times that of the arc. Towards the violet end of the spectrum the relative importance of the sun's rays is less, owing to atmospheric absorption. The solar rays are relatively stronger than those of the arc in all parts of the infra red spectrum known until lately, although in the extreme portions recently investigated the rays of the arc are more powerful. When allowance is made for atmospheric absorption it is found that the superiority of the sun's rays over those of the arc continuously increases in proceeding from the ultra red to the ultra violet portions of the spectrum, the number expressing the ratio being 4 in the extreme red, 10 in the orange and red, and 26 in the extreme violet. These results show that there is considerable atmospheric absorption in the extreme parts of the spectrum, although in the red portions very little occurs.

THE 1890 edition of "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK is now ready. No pains have been spared to make the Directory both accurate and complete, and the Handbook Section will be found to contain several valuable additions. Amongst the new features of the Handbook are a full Digest of the Law relating to Electric Lighting, which has been specially prepared for this work by Mr. A. C. CURTIS HAYWARD, and the Tables of Limiting Currents for Electric Light Conductors, recently drawn up by Mr. A. E. KENNELLY. The growth of this publication has been contemporaneous with that of the electrical industry. In 1883 the Directory consisted of 72 pages; the 1890 edition contains 850 pages. In 1883 it was found possible to include the various branches of the industry under less than 60 headings; in 1890 400 headings scarcely suffice.

Exhibition at Liege.—A National and International Exhibition is to be opened at Liège in June next.

Restoration of Telegraphic Communication.—Telegraphic communication with the Isle of Skye has been restored.

Berlin.—The Niederschlesisch Märkischen Bahn Station at Berlin is to be lighted by electricity at an estimated cost of 103,000 marks.

Telephonic Development.—The first message from Birmingham to St. Helens on the new extension wires of the National Telephone Company was transmitted on Friday last *vid* Manchester.

London Chamber of Commerce.—Among the companies elected members of the London Chamber of Commerce, at the January Council meeting, was the Metropolitan Electric Supply Company.

A Costly Telegram.—The Italian papers state that the telegram sent to Rio de Janeiro by the King of Italy to the son of the Duke d'Aosta, announcing the Duke's decease, contained 1,200 words, and cost £534 1s. 3½d.

Dr. Werner von Siemens.—Dr. Werner von Siemens, who has just retired from business, is engaged in writing his autobiography, which will, it is stated, contain some interesting details of the development of the Siemens and Halske business.

Cheltenham.—At the last meeting of the Town Council a communication was read from Messrs. Laing, Wharton, and Down, intimating that they had withdrawn their application

Digitized by Google

for a Provisional Order, in deference to the application of the Corporation.

The Lighting of the City.—At the last meeting of the Commissioners of Sewers, a letter from the Brush Electrical Engineering Company asking that the western division of the City might be included in their electric lighting contract as well as the central, was referred to a committee.

Royal Institution.—As will be seen by our advertisement columns, Lord Rayleigh will begin a course of seven lectures on "Electricity and Magnetism" on Saturday, February 15th. As these lectures are on Saturdays, in the afternoon, it is anticipated that they will be very largely attended by students and others.

Wrexham.—At the last meeting of the Town Council there was a lengthy discussion on the draft Provisional Order applied for by the Wrexham and District Electric Supply Company. It was finally decided to confirm the minutes of the Lighting Committee, and to lodge the necessary objections to the Order.

Camberwell Vestry.—At the last meeting of this Vestry the report of the General Purposes Committee on the subject of the electric lighting Orders was adopted by 25 to 22, consent being given to the Orders of the London Electric Supply Corporation and the Electric Construction and Maintenance Company.

The Halifax-Bermudas Cable.—It is announced that the English Government have prolonged the time originally allowed for the laying of this cable to the 24th June. The company intend, it is also stated, to complete the scheme by telegraphically connecting the Bermudas with the Bahama Islands and Jamaica.

Bath.—At the last meeting of the Town Council the Special Electric Lighting Committee presented their report on the work by Mr. Massingham, in pursuance of the contracts between him and the local authority. In moving the adoption of the report, Mr. Sturges expressed the opinion that the Company had worked very well and met them fairly.

Breslau.—The Town Council of Breslau has accepted a tender for the supply of electric lighting plant, sufficient to run 7,500 to 8,000 16 candle-power lamps simultaneously. Accumulators capable of supplying 400 lamps for five hours will also be provided to meet the demand for the light during the day. The cost, according to Messrs. Siemens and Halske's tender, will be 910,000 marks.

Telephonic Communication between Berlin and Vienna.—The proposed telephone trunk wire between Berlin and Vienna, a distance of about 400 miles, is receiving much attention. The preliminary experiments have been made, and with such success that negotiations have been commenced between the two Governments with a view to an agreement for the immediate construction of the line.

Tunis.—The Société Générale des Téléphones is about to undertake the construction of a telephone system in Tunis. The subscription to the exchange is to be 200fr. per annum, the subscriber having to pay, in addition to the annual rental, a first charge of 150fr. per mile of wire between his house and the exchange, and 75fr. for the apparatus installed. A two years' subscription must also be guaranteed.

College Lighting.—An installation comprising eighty 16 candle-power incandescents has just been fitted up in the School of Anatomy, Trinity College, Dublin, by the firm of J. Edmundson and Co., of Capel-street. The motive power is supplied by a 7 horse-power nominal Otto gas engine, which actuates a 5-unit Elwell-Parker dynamo. In addition there is a storage battery capable of supplying fifty 16-candle lamps for ten hours.

London Tramways Company.—An extraordinary general meeting of the shareholders of this company was held on Tuesday to confirm the special resolution passed at the general meeting of the shareholders held in January, approving a Bill deposited by the company in Parliament, entituled "London Tramways Company (Limited) Bill, 1890." The object of the Bill is to allow of the company making use of electric or any other power which may be discovered in the drawing or driving of their road cars. The resolution was formally approved.

Chelmsford.—At the meeting of the Town Council last week, it was announced that the Board of Trade report on the subject of the electric light wires and posts had been received, but that being a lengthy document it had not yet been perused by the Lighting Committee. The Mayor, in reply to a question, said that he had been informed that the electric light might be ready in a fortnight.—According to the *Essex Telegraph*, much of the wire which has been put up at Chelmsford will have to be taken down, and other wire substituted for it. Messrs. Crompton and Co. are not satisfied with the quality of the wire in question, its conductivity being, they allege, very low.

The Relation between Magnetic Properties and Atomic Weights.—Success has not hitherto attended attempts to apply the periodic law to the classification of elementary bodies according to their magnetic properties. M. Bachmetieff, however, claims to have succeeded somewhat better than others. He has constructed a curve, the abscissæ of which are the atomic weights, and the ordinates the magnetic values of the elements—paramagnetic values being measured above the line, and diamagnetic values below it. The result is an irregular but continuous sinusoid. The curve is, of course, quite arbitrary in several parts, since the necessary data are not yet forthcoming.

The Telegraph in Persia.—The Director-General of Indian Telegraphs, in his yearly report, states that in February last an application was received from the Persian Government for material for the construction of a line of telegraph from Burujird to Muhammera, the object being to facilitate the opening up of the Karun River as an international trade route. The stores asked for were supplied in May last. During the year reported on a telegraph line, 60 miles long, from Ispahan to Kalleh Kazir, was constructed by the officials of the Indo-European Telegraph Department, at the request of His Royal Highness the Zil-es-Sultan, who has expressed his gratitude for the service in the warmest terms.

Liverpool.—At the last meeting of the shareholders of the Liverpool Tram and Omnibus Company, the chairman, Sir David Radcliffe, referred to the electric cars which were about to be tried in Liverpool, and said the delay in trial was on account of the steep gradients, which necessitated the designing of special cars and apparatus. A letter was read from Lord Bury explaining these points, and stating that the experience gained by his company on the North Metropolitan Tramway at Barking compelled them to design motors of greater power than they had at first anticipated, that the experimental car was nearly completed, and that all the difficulties, as far as they could see, had been overcome.

Lambeth Vestry.—At the last meeting of this Vestry the Electric Lighting Committee reported that draft orders had been lodged with the Board of Trade by the London Electric Supply Corporation, Metropolitan Electric Supply Company, House-to-House Electric Light Supply Company, and the Electric Construction and Maintenance Company. Having considered the whole of the orders, they recommended that assent should be given to the House-to-House Company and the Electric Construction Company, and that objections should be lodged against the Orders asked for by the London and Metropolitan Companies. An amendment was, however, carried to the effect that objections should be lodged against all four companies.

St. James's Vestry.—At the last meeting of this Vestry the Lighting Committee reported that the mains being laid in the streets by the London Electric Supply Corporation were at less depth than 6in. below the surface of the pavement, and they regarded the same as a source of great danger. They had caused notice to be served upon the company requiring them to take up the whole length of main already laid by them under the streets of the parish, differing from the specimen main submitted and assented to by the Vestry, and to discontinue laying mains in this parish, except as assented to by the Vestry. They had authorised the vestry clerk to take further action, if necessary, to restrain them by an injunction. The report was adopted *nem. con.*

Salzburg.—The Salzburg central station is interesting from the fact that the dynamos are intended to be run by day for a

Digitized by Google

mountain railway. The station is established near the Salzbach, which runs through the town. The plant comprises two steam-engines of 30 and 60 horse-power, which drive three Siemens and Halske shunt-wound dynamos, of 140 volts and 125 amperes, at 940 revolutions. The cables are concentric and armoured. At the present moment the station only supplies some 500 lamps, but its plant capacity is equivalent to 1,200 lamps. It is proposed to run an electric railway to the summit of the Monschberg. Some 18 horse-power will be required for this work, and a single dynamo at the station will therefore suffice to supply the necessary current.

The Destruction of the Edison Station in Pearl-street.—In a letter to a M. Vernes, published in the last number of the *Bulletin International de l'Electricité*, Mr. Edison writes as follows:—"I thank you for your letter of the 10th instant. The fire at the Pearl-street station took place on Thursday, and completely destroyed it. On Saturday our men set to work, and by the following Saturday current was again being supplied from Pearl-street to the 20,000 lamps fed by the old station. This *tour de force* was accomplished in six days of 24 hours. Would you be capable of such a feat in Paris? The losses will not be great, since the damage done by the fire is covered by insurance, and the cost of operating the new station will be 30 per cent. less than that of operating the old."

Central London Railway Scheme.—At the last meeting of the City of London Tradesmen's Club an amendment was carried that the club should not give unqualified support to the Central London Railway until the City and Southwark Subway has proved the great success foreshadowed by Mr. Greathead.—At the last meeting of the City Commission of Sewers a petition was presented from owners of land and property and lessees and occupiers of houses in Holborn, Holborn-viaduct, Newgate-street, Cheapside, Poultry, King William-street, and Arthur-street, against the Central London Railway scheme, on the ground of the injury it would occasion them, and the enormous inconvenience which would result to the public. The petition was referred to the Finance and Improvement Committee.

Bridlington.—The action taken by the local board at its last meeting opens up the possibility of the town being without the means of public lighting after the 25th proximo. Tenders had been advertised for the lighting of the district either by gas or electricity. Two tenders had been received—one from the gas company, offering to light by gas at 35s. 6d. per lamp for 1,200 hours, and the other from an electric lighting company on the Thomson-Houston system, who would put down 28 arc lamps and 160 Edison-Swan incandescent lights for £900 a year on a contract for five years. The motion in favour of accepting the gas company's tender was lost by one vote, while that in favour of the electric lighting scheme was lost by two votes. Both tenders were thus rejected, and if some arrangement be not entered into before the expiration of the present contract for gas the town will be left in darkness.

The Edison General Electric Light Company.—At the first annual meeting of the Edison General Electric Light Company the report of the company, says the *Iron Age* of New York, showed the great expansion of the business of electric lighting during 1889, and indicated that there would be even greater growth in 1890. One item in the report says: "The new business in sight in every department is in such a state that, if the company succeed in increasing their capacity sufficiently to execute it, the gross receipts in 1890 will be twice as large as in 1887-1888." The number of *employés* in the Schenectady shops in 1888 were 750, last year 1,300, and this year it is proposed to increase the working force to 2,000. A large number of men are also employed in other places and in the other departments of the company's works. During the past year 2,500 dynamos and motors were manufactured. The number of street-railway cars equipped with motors was 551.

The Electrolytic Preparation of Sodium and Aluminium.—In the course of his researches on the electrolytic preparation of aluminium M. Roger has been led to mix the salt of aluminium with an alloy of lead and sodium, a method which he claims greatly increases the yield of aluminium. The lead-sodium alloy is obtained by the electrolysis of a solution of sea salt, a lead plate being employed as cathode. In one of the first experiments a current of 80 amperes at 24 volts traversed four crucibles arranged in series, each of which contained the following mixture:—One part of cryolite, three parts of sea salt, and 27 grammes of lead. After six hours 15 grammes of aluminium were recovered, and there remained at the bottom of the crucibles a quantity of fused sodium and cryolite. According to M. Roger this process will enable 500 grammes of aluminium to be obtained by the expenditure of 1 horse-power for 24 hours, or 80 per cent. of the theoretical maximum yield.

The Pont-de-Vaux Central Station.—Pont-de-Vaux (Ain), the population of which is only 3,500 persons, is probably the smallest town in the world possessing a central lighting station. The system adopted is the modified Edison three-wire system, with feeders, and the plant consists of two steam engines, each of 40 horse-power, driving by belting two Bovy dynamos, having an output of 200 amperes and 137 volts. For the public lighting only fifty 16 candle-power lamps have as yet been put up. The station is situated from the most distant lamp only half-a-mile. To avoid the use of two dynamos a compensating device to re-establish the equilibrium between the two circuits, as first suggested by Prof. Elihu Thomson, has been employed, and each of the two circuits is fed by a dynamo connected to a compensating system, consisting of two small dynamos run in parallel. Khotinsky lamps are employed, and current is charged for at the rate of £2 per 16 candle-power lamp per annum.

Telegraph Wires across the Forth Bridge.—The telegraph department of the North British Railway are at present engaged in laying telegraph wires across the Forth Bridge. Up till now telegraphic communication between the north and south of Scotland has been maintained by means of cables under the Forth, a system which has proved very expensive owing to the damage frequently caused to the cables by ships dragging their anchors. The erection of the bridge, however, does away with necessity for submarine wires, and when the communication by the viaduct has been properly established, it is proposed to remove most of the cables in the Firth. Altogether fifty wires are being laid across the bridge, enclosed in two 2-inch iron tubes—twenty for the use of the Railway Company, and thirty for the use of the General Post Office. Three cables will be lifted at Queensferry, and four at Burntisland, but the cable from Granton to Aberdour will be allowed to remain.

Islington Vestry.—At the last meeting of this Vestry the Special Committee appointed by the Vestry to inquire into the subject of electric lighting reported that neither the order of the Brush Electrical Engineering Company nor that of the House-to-House Electric Light Supply Company made provision for generating stations, and only provided for the deposit of £1,000 each in respect to the areas affected by the Orders. The Committee was of opinion that the two companies should be required to deposit at least £1,000 each in respect of their works in the parish of Islington alone. The Committee further recommended that all reference to the County Council in connection with the control of overhead wires and the breaking-up of streets in the parish be omitted, and that the Brush Company be required to omit the clause enabling it, with the sanction of the Board of Trade, to transfer its Order. The report was adopted, and the Committee was empowered to serve the requisite notices of objection.

The Requisites of a Mining Motor.—In a short article on "The Conditions of Efficiency in Electrical Mining Machinery," in the *Electrical World* of January 4th, Dr. Louis Bell sums up the requisites of a good mining motor in the following terms:—"The distribution of power from a central station to all the portions of a distant mine by any of the methods in use up to the present involves so serious a loss that electricity need fear no severe competition on the ground of efficiency. Consequently, the point to be aimed at in building electrical mining machinery is to make a strong, well-insulated motor, easy to manage and to repair, and which will do the work required. If the armatures and fields can be made thoroughly waterproof and able to withstand a reasonable amount of heating, the question of electrical efficiency may be put aside for the present. When a motor has been built that will do this rough mining

Digitized by Google

work, and do it without the necessity of frequent attention or repairs, it will be time enough to look for a theoretical efficiency."

Indo-European Telegraph Department.—The receipts of the Indo-European Telegraph Department for 1889 amounted to 11,44,600 rupees, as against 10,35,235 rupees in 1887-88, the increase being mainly due to the fact that there was more traffic in consequence of breaks in the Eastern Company's cables in August and September, 1888. The working expenses of the year were 9,53,223 rupees, and the net revenue 1,91,377 rupees, the increase of expenditure being mainly due to the cost of extensive repairs and renewals that have been carried out. It has been decided to lift and thoroughly rehabilitate the 1864 cables throughout, at a cost of 7,03,000 rupees, to be distributed over three or four years. During this year, 201 knots of cable were expended in renewals and repairs. It is satisfactory to find that throughout the year there was no break on the Persian Gulf Section between Kurrachee and Bushire which affected communication between the East and Europe. On the Persian Section the interruptions, owing to the severity of the winter, were rather in excess of those of the year 1887-88, and the period of total interruption, mainly due to a great snowstorm at Shiraz, amounted to 50 hours 24 minutes.

Electric Currents in the Skin.—An interesting study has been lately made by Herr Tarchenoff of electric currents in the skin from mental excitation. Unpolarisable clay electrodes, connected with a delicate galvanometer, were applied to various parts—hands, fingers, feet, toes, nose, ear, and back; and, after compensation of any currents which occurred during rest, the effects of mental stimulation were noted. Light tickling with a brush causes, after a few seconds' period of latency, a gradually increasing strong deflec ion. Hot water has a like effect; cold, or the pain from a needle-prick, a less. Sound, light, taste, and smell stimuli act similarly. If the eyes have been closed some time, mere opening of them causes a considerable deflection from the skin of the hand. It is remarkable that these skin-currents also arise when the sensations are merely imagined. Mental effort produces currents varying with its amount. If a person is in tense expectation, the galvanometer mirror makes irregular oscillations. In all the experiments it appeared that, with equal nerve excitation, the strength of the skin-currents depended on the degree to which the part of the skin bearing the electrodes was furnished with sweat-glands.

New Submarine Cables.—The *Journal Télégraphique* announces that the concession granted to the Pedro Segundo Telegraph and Cable Company having been revoked, the Governor of Surinam, on September 18th, granted a concession to the Société Française des Télégraphes Sous-Marins. Within eighteen months from the date of the granting of the concession Paramaribo is to be connected by one or more cables with some point on the system of the Société Française, and as soon as a concession has been obtained from the French Government, a cable is to be laid between Paramaribo and Cayenne. The tariff between Surinam and various places will be as follows:—Venezuela, 6fr.; Curaçao, 5fr.; St. Dominica, 4fr. 50c.; St. Domingo, 5fr.; Martinique, 2fr.; Guadaloupe, 2fr. 50c.; New York, 8fr.; Cayenne, 1fr. Official messages will be taken at half-rates. The Government of Surinam will, moreover, levy a tax of 10 centimes per word on all messages sent to or from that colony. The Société Française will receive an annual subsidy of 50,000fr., and the concession is to last 60 years, during the first 20 of which no other concession may be granted by the colonial authorities.

The Stuhl Electrical Alarm Thermometer.—The action of most electrical alarm thermometers consists in causing the expansion of the mercury to complete the alarm circuit by coming in contact with a platinum wire connected across the tube of the instrument at the required height. The disadvantage of these thermometers is that they can only be used to indicate one temperature, and the following arrangement has been devised by M. Stuhl to overcome this defect:—Below the thermometer-scale, but above the bulb, he places a glass ball, which only offers a capillary passage to the expanding mercury; one end of the alarm circuit is permanently in contact with mercury in the bulb, the other end of the circuit terminates immediately underneath the glass ball. To set the thermometer it is only necessary to heat it to the required temperature, and then allow it to cool. A portion of the mercury has by this operation been forced past the obstacle, and remains there; the rest of the mercury on cooling sinks into the bulb. Whenever the mercury again expands and touches the platinum contact under the glass ball, a battery and bell in the alarm circuit results in the ringing of an alarm. If it is required to make the alarm ring at a higher temperature, the mercury has only to be heated to that degree. If an alarm is wanted at a lower temperature, the mercury above the ball must be made to fall into the bulb by giving the thermometer a sharp twisting motion.

Earth Currents.—In a Paper read before the Naples Academy of Sciences, Signor Palmieri gave an interesting account of some earth current phenomena recently observed by him in connection with an ordinary overhead telegraph line, five miles long, running from Resina to the Vesuvius Observatory, *i.e.*, from S.W. to N.E. Previous observers have noted the fact that in wires placed in the magnetic meridian, the direction of the earth current was from north to south, and in wires placed equatorially from east to west. Accordingly in the wire experimented on by Signor Palmieri the current *ought* to have been from N.E. to S.W., instead of from Resina to Vesuvius as was the case. Matteucci has observed that in wires inclined at an angle to the horizon, the earth currents are always in an upward direction. Now the difference in level between Resina and the Observatory was nearly 2,000ft. Signor Palmieri, therefore, extended the line from the Observatory in practically the same direction for a distance of nearly 200 yards, and earthed it on the reverse slope of the mountain 52ft. below. If the new line were earthed at the Observatory, the galvanometer showed that a current of less intensity but opposite in direction to the Resina-Vesuvius current was flowing in the wire. If the Resina-Vesuvius line were joined up to the extension line, the earths now being at Resina and at the point 52ft. below the Observatory on the reverse slope of the mountain, the galvanometer deflections were found to be proportional to the algebraical sum of the current intensities. Signor Palmieri concludes his remarks by pointing out that previous observations which did not take this phenomenon into account are entirely vitiated.

The Action of a Long-Continued Electric Discharge on Iodine.—In a Paper recently read before the St. Louis Academy of Science Mr. C. Luedeking describes some experiments undertaken by him for the purpose of studying the effects of the electric discharge on iodine vapour, when continued over a long space of time. The researches of V. Meyer showed that with increasing temperature the vapour density of iodine becomes rapidly less than what is demanded by theory, finally reaching two-thirds of the theoretical value. Later, J. J. Thomson showed that the silent discharge produces the same phenomena of anomalous densities that were observed by V. Meyer for high temperatures. For the purpose of his investigations Mr. Luedeking employed four Grove cells energising a 2-in. spark Ruhmkorff coil. The wires of the coil were connected with heavy platinum wires, sealed in a small, heavy glass tube, with their ends opposite and ½-in. apart from one another. In this tube, 0·036 grm. of iodine was sealed hermetically. By gentle heat it was then vapourised in part. The spark was now passed incessantly for three weeks, day and night, and the character of the light phenomena watched as carefully as possible. As the experiment advanced, the colour of the contents of the tube gradually changed, losing the rich deep violet tint that it had at first, very much resembling bromine vapour in appearance, and passing through this stage, becoming more and more faint, until, at the end of the afore-mentioned time, the tube was entirely colourless, and evidently all iodine had disappeared. The platinum poles were much corroded and roughened; during the discharge, the ends were constantly at a bright red heat; the spark itself had a livid appearance, was uncertain in its course, changing frequently. The sides of the tube were affected as if by hydrofluoric acid. Mr. Luedeking attributes the disappearance of the element iodine to its uniting with the constituents of the glass, and he thinks that under the influence of the electric discharge iodine certainly acquires superior chemical affinities, attacking the substance of the glass, and forming iodides, and probably also some iodates.

MAGNETISM IN IRON AND OTHER METALS.*

BY PROF. J. A. EWING, F.R.S.

V.

(*Continued from page 313.*)

§ 27. Distribution of Free Magnetism in the uniformly magnetised Ellipsoid.—Within the ellipsoid the lines of force **H**, of magnetisation **I**, and of magnetic induction **B**, lie, as in Figs. 7 and 8, straight and parallel to the lines in the undisturbed field. Since the magnetisation is uniform the free magnetism resides wholly on the surface. To see how it is distributed over the surface we have to remember that **I** is the surface density of free magnetism per square millimetre on every part of an imaginary *surface formed by taking an end*

Fig. 9.

elevation of the ellipsoid—that is to say, by projecting it upon a plane which is perpendicular to the direction of magnetisation. We may therefore obtain a diagram showing the true surface density of free magnetism on the actual surface of the ellipsoid, by supposing the ellipsoid shifted through a very small distance in the direction of magnetisation, so that a meniscus is formed on either side of the middle, between the old and the new positions. Then the thickness of the meniscus is proportional to the surface density of the free magnetism. Thus in Fig. 9 the original ellipsoid is C A C′ A′. By shifting it through the small distance C D or C′ D′, we get the positive meniscus C′ D′, which is a diagram of the surface density of positive free magnetism on one half, and the negative meniscus C D, which in the same way represents the negative free magnetism on the other half. The free magnetism, though densest at the ends, extends towards the middle, and it is only at the equatorial line that there is none. It is easy to show, by referring to the geometrical properties of an ellipsoid, that the distribution which has been described results in making the total quantity of free magnetism on any narrow zone taken perpendicular to the direction of magnetisation proportional to the width of the zone and to its distance from

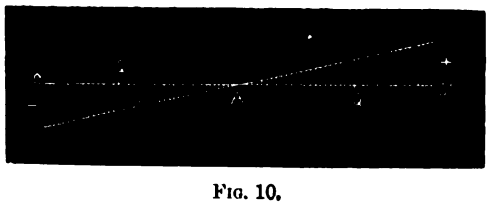

Fig. 10.

the equator A A′. In other words, what we may call the linear distribution of free magnetism in the direction of the axis C C′ is correctly represented by the height of the lines above and below C C′ in Fig. 10.

Again, in regard to linear distribution, it follows that what we may call the centre of the negative magnetism is at Q, two-thirds of the distance A C from A, and the centre of the positive magnetism is at Q′, two-thirds of the distance A C′ from A. The distance Q Q′ is two-thirds of C C′, or $\frac{4}{3}c$.

§ 28. Moment of Ellipsoid.—The whole quantity of positive or of negative magnetism is $\pi a^2 \mathsf{I}$—namely, **I** multiplied by the area of the equatorial section, which is a circle in the special case we have taken, the case of an ellipsoid of revolution with $a = b$. On *distant* external points the action of the magnetised ellipsoid will be the same as if this quantity of positive magnetism were gathered at Q, and an equal quantity of negative magnetism at Q′. The magnetic moment of the ellipsoid is therefore

$$\pi a^2 \mathsf{I} \ \overline{\mathrm{Q}\mathrm{Q}'} = \frac{4\pi}{3} a^2 c \, \mathsf{I}.$$

But we might have obtained this result more directly. Since **I** is by definition the moment per unit of volume (§ 7), and the volume of the ellipsoid is $\frac{4}{3}\pi a^2 c$, the moment is $\frac{4}{3}\pi a^2 c \, \mathsf{I}$, as above.

§ 29. Application to the Case of a Sphere.—When c is equal to a, the eccentricity e is 0, and the ellipsoid becomes a sphere. We then have the case of which Figs. 5 and 6 furnish illustrations. The sphere is uniformly magnetised, but even when the material of which it is made is exceedingly permeable, the magnetisation is by no means strong, because the free magnetism which becomes developed on the surface causes the true magnetic force **H** in the interior to be much less than the original magnetic force **H′** due to the external field.

By applying the general formula of § 26 to find the value of **N** in the expression

$$\mathsf{H} = \mathsf{H}' - \mathsf{N}\,\mathsf{I},$$

it may be shown that for a sphere $\mathsf{N} = \frac{4}{3}\pi$, so that

$$\mathsf{H} = \mathsf{H}' - \frac{4\pi}{3}\mathsf{I}.$$

Dividing by **H** we have

$$1 = \frac{\mathsf{H}'}{\mathsf{H}} - \frac{4}{3}\pi\frac{\mathsf{I}}{\mathsf{H}} = \frac{\mathsf{H}'}{\mathsf{H}} - \frac{4}{3}\pi\kappa.$$

Hence, the proportion which the true magnetic force **H** bears to the force in the undisturbed field is

$$\frac{\mathsf{H}}{\mathsf{H}'} = \frac{1}{\frac{4}{3}\pi\kappa + 1}.$$

This shows that when the material is very susceptible, so that κ is large, the true force **H** is only a small fraction of **H′**. To take a practical instance, the susceptibility of soft iron to weak magnetic forces, such as those produced by the earth's field, is about 20. Assigning this value to κ, we have $\frac{\mathsf{H}}{\mathsf{H}'} = \frac{1}{85}$ approximately. Thus the true magnetic force within a spherical ball of soft iron placed in the earth's field is only about the $\frac{1}{85}$th part of the force in undisturbed parts of the field, and the magnetisation **I** which the ball will take up is only about $\frac{1}{85}$th of that which would be taken by a very long rod of the same material set lengthwise in the direction of the lines of terrestrial magnetic force.

Again, as to the magnetic induction in the sphere and its relation to the permeability, we have (remembering that the permeability $\mu = 4\pi\kappa + 1$)

$$\mathsf{B} = \mu\mathsf{H} = \frac{\mu\mathsf{H}'}{\frac{4}{3}\pi\kappa + 1} = \frac{3\mu}{\mu + 2}\mathsf{H}'.$$

When μ is exceedingly large, the factor $\frac{3\mu}{\mu+2}$ approximates to 3. Hence, in a sphere of very permeable material, the number of lines of induction through the sphere (per square centimetre of section) is nearly three times the number of lines in the undisturbed field. This is the case in the sphere of Fig. 6 (the proportion of the closeness of the lines inside to that of the lines outside at a distance from the sphere being $\sqrt{3}$ to 1, as seen on the plane of the diagram). The student should note that when the permeability of the sphere is great, its exact value has very little influence on the number of lines of induction that pass through the sphere, and hence a spherical ball would be a very bad form of body to select if we wished by measuring the induction to determine the permeability of the material. A small error in the form of the sphere would, in fact, have more influence in altering the amount of the induction than a large difference in the value

* All rights are reserved.

Digitized by Google

of μ or of κ; so that, as Prof. Chrystal has well put it, the experimenter would be testing the accuracy of his instrument-maker rather than the magnetic susceptibility of his material.*

§ 30. The same objection would apply, though in a slightly less degree, to a *short* ellipsoid. By way of illustrating this further, Fig. 11 has been drawn to show in a general manner the induction through an ellipsoid, and the distortion which it produces in an originally uniform field, when the axes have the proportion of 4 to 1, the material being assumed to have indefinitely great permeability. With this proportion between the axes, N, by the formula (1) of § 26, is 0·246, and for every line of force (per square centimetre) in the undisturbed field there are 13·3 lines of induction (per square centimetre) within the ellipsoid. The space between the lines within the body is therefore narrower than the space between the lines in any distant part of the field in the proportion of 1 to $\sqrt{13·3}$. The permeability might vary widely without materially affecting the amount of induction, and the figure may be accepted as representing very nearly what would happen if the ellipsoid were of soft iron.

§ 31. **Application to the Case of a Long Cylindrical Rod of Circular Section Magnetised Transversely in a Uniform Field.**—This case, of which an example is furnished by a long wire stretched in the earth's field in a direction perpendicular to the lines of force, is deducible from the general case of the ellipsoid by making one of the axes infinite. This gives $N = 2\pi$, so that $H = H' - 2\pi I$.

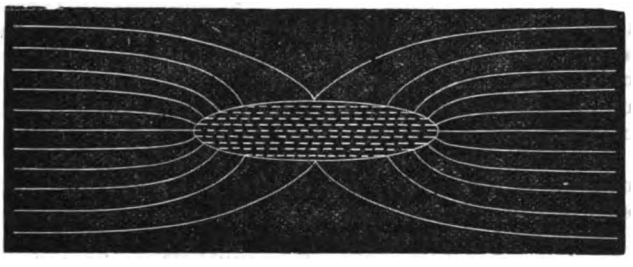

FIG. 11.—Short ellipsoid of infinitely permeable material in a uniform field.

Hence, $\frac{H}{H'} = \frac{I}{2\pi\kappa + 1}$, and $\frac{B}{H'} = \frac{2\mu}{\mu + 1}$.

Thus, when μ is very large, as it is in soft iron, the transverse induction B across the wire approximates a value which is twice that of the external field. This is a very small induction compared with that which the same wire would take longitudinally if it were set lengthwise instead of crosswise in the field (compare § 15 above). If we assume κ to be 20, the proportion of the induction in the two cases is about 1 to 127.

It follows from this that when we hang a wire vertically in the earth's field, the transverse magnetisation due to the horizontal component of the earth's field is so small that account need not in general be taken of it, and the same thing is true of the transverse magnetisation of a wire laid horizontally in the earth's field.

§ 32. **Case of a Thin Disc Magnetised in the Direction of the Thickness by a Uniform Field.**—We may find the true magnetic force within a disc or large thin plate magnetised normally in a uniform field from the fact that the lines of induction B within the disc are continuous with the lines of force H′ in external space, and if the disc is very wide in comparison with the thickness, the lines go straight through it without sensible distortion. Thus $H' = B = 4\pi I + H$, so that $H = H' - 4\pi I$, $\frac{H}{H'} = \frac{I}{\mu}$, and the induction within the disc is the same whatever be the permeability of the material.

§ 33. **Long Ellipsoid: Influence of the Length on the Magnetising Force.**—Returning now to the general case of a long ellipsoid of revolution placed longitudinally in a uniform magnetising field, it is interesting to notice to what extent the uniform magnetisation of the ellipsoid itself affects the magnetic force, when we assume various values as the ratio of length ($2c$) to transverse diameter ($2a$).

In the formula

$$H = H' - NI,$$

we may write $\frac{B - H}{4\pi}$ for I (by § 13), and if the material is very permeable, so that B is large compared with H, this will be very nearly equal to $\frac{B}{4\pi}$ simply. Hence in an ellipsoid made of very permeable material, such as iron,

$$H = H' - \frac{N}{4\pi} B, \text{ very nearly.}$$

The following values of N and also of $\frac{N}{4\pi}$ have been calculated by means of the expressions in § 26 for ellipsoids in which the ratio of length to breadth is 50, 100, 200, 300, 400, and 500 respectively.

Ratio of Length to Breadth $\left(\frac{c}{a}\right)$	N	$\frac{N}{4\pi}$
50	0·01817*	0·001446
100	0·00540	0·000430
200	0·00157	0·000125
300	0·00075	0·000060
400	0·00045	0·000037
500	0·00030	0·000024

* The approximate formula (2) of § 26 gives 0·01812. For the longer ellipsoids the values of N calculated from it may be taken as correct.

Since $H = H' - NI$, $\frac{H'}{H} = \frac{NI}{H} + 1 = N\kappa + 1$. The proportion which the resultant force H bears to the original force H′ in the undisturbed field,

$$\frac{H}{H'} = \frac{1}{N\kappa + 1}.$$

By the help of the above table it is easy to find this proportion, for an assigned ratio of length to breadth, when the susceptibility of the material is known.

As an example we may take $\kappa = 200$ as a representative value of the susceptibility in soft iron when subjected to a moderately strong magnetic force. Suppose that the ellipsoid is 100 diameters long, then

$$\frac{H}{H'} = \frac{1}{0·0054 \times 200 + 1} = \frac{1}{2·08}.$$

In other words, the magnetic force actually operative within the metal—as reduced by the magnetism of the piece itself—is in that case rather less than one-half the force due to external causes.

§ 34. **Residual Magnetism and Retentiveness.**—When a piece of any one of the strongly magnetisable metals—iron, steel, nickel, or cobalt—is magnetised by applying magnetic force, and the externally-applied force is then withdrawn, it is found that the magnetisation does not wholly disappear. What remains is usually called the residual magnetism, and metals which retain residual magnetism when the external magnetic force is withdrawn are said to possess retentiveness.

We shall see later that this retention of residual magnetism, when the externally applied magnetising force is withdrawn, is only one instance of a general tendency which these metals exhibit to resist any change in their magnetic state.

§ 35. **Self-Demagnetising Force.**—In connection with the subject of retentiveness it is of the first importance to notice that though the externally applied magnetic force be withdrawn from a magnetised piece, there is in general some magnetic force in action. This force is due to the residual magnetism itself, and its tendency is to *reduce* the residual magnetisation. In a bar magnet, for instance, the residual magnetism at and near the ends of the bar produces a magnetic force acting in the direction of the length and tending to demagnetise the bar. In a ring magnet uniformly magnetised we get rid of this self-demagnetising force by having the ends, so to

* Article "Magnetism," *Encyc. Britannica*. Ninth Edition

Digitized by Google

speak, brought together. In an exceedingly long bar the self-demagnetising force becomes insignificant because the ends are far removed from most parts of the bar. The residual magnetism in a ring or a very long rod will therefore be greater, other things being equal, than in a short rod. Indeed, so much is this the case that, in dealing with soft annealed iron, we shall find almost no residual magnetism if we experiment with rods the length of which is only 10 or 20 times their diameter, because in these rods the self-demagnetising force is sufficient to remove the residual magnetism almost completely, whereas a rod 400 or 500 diameters long will be found to retain a very large proportion of its induced magnetism when the inducing force is withdrawn. Hence the term residual magnetism has one meaning when it is used to describe the magnetism that remains when magnetic force is completely withdrawn without any reverse force being applied, an experiment which can be made if we use an exceedingly long rod or a ring magnet; and it has another and quite different meaning when it is used to describe the magnetism which a baror other short piece will retain in opposition to the demagnetising force which it exercises upon itself.

§ 36. **Self-Demagnetising Force in Ellipsoids.**—In the case of an ellipsoid, uniformly magnetised, the self-demagnetising force is uniform throughout the body, and its value is

$$\mathsf{N}\,\mathsf{I},$$

where **N** has the same meaning as in § 26 and **I** is the *residual* intensity of magnetisation.

To get an idea of what this may amount to in actual cases, we may take 1,000 C.-G.-S. units as a residual value of **I**, which is commonly enough found in the magnetisation of iron. When an ellipsoid is 200 times as long as it is broad the value of **N** is 0·00157 (by § 32), and a residual intensity (**I**) of 1,000 would therefore produce a self-demagnetising force of 1·57. The experimental results which will be given later will show that a force of this magnitude is by no means insignificant, and that it would, in fact, be sufficient to remove a large part of the residual magnetism. It is only when the length is as much as 400 or 500 times the transverse diameter that the self-demagnetising force in a material so susceptible as iron becomes nearly negligible.

(To be continued.)

UNDERGROUND MAINS.

BY G. L. ADDENBROOKE.

IV.

(Continued from page 315.)

Mr. Crompton's System of Mains and Conduits.

Mr. Crompton, with his usual energy, has made a vigorous and carefully-thought-out attempt to satisfactorily solve the question of distributing electricity, more particularly at low pressures, though there is no reason why his system, with some modifications, should not be useful and convenient for high pressures also.

Like most things of the sort, this system has been gradually led up to and perfected as the result of a long series of observations and experiences. When starting the Kensington Central Station Mr. Crompton was at the outset favoured on the Kensington Court estate itself, which is a large square of handsome modern residential houses, by the presence of a subway all round and next the houses. It was determined to light the houses by bare mains run on insulators attached to the sides of this subway. These insulators were made of china and glass, and had a notch in the top to take a flat strip of copper edgewise. And here came the first difficulty. A flat strip of copper, however carefully rolled, will have in long lengths many uneven tensions in it between the two opposite sides of its breadth, and consequently when standing on its edge is almost certain to buckle about and refuse to lie straight. Even when iron carriers were used on the top of the insulators instead of the notches in the glass, the strip still proved refractory. It was then determined to let the strip have its way, so to speak, and to lay it flat. When this was done, most of the troubles vanished; and it was found that the strip could be got to lie quite even and straight in properly-shaped notches in the top of the insulators. This, then, was the beginning of the system. The bare copper strips were cheap, and worked well; and it was determined to try and extend the method when the mains were run over a larger area, and had to be carried under the pavements and roadways instead of being fixed to the side of a subway.

The first requisite was to form the conduit, and that is done in this way: The pavement of the footway is taken up, and the ground excavated to a depth of 18in. or 2ft., when circumstances will allow, or, if they do not, to a depth of 10 or 12in. only, which is all the room which can be got in places. A long trench about 15in. broad is then formed of concrete, carefully levelled and as straight as possible, the curves, where such exist, in the line of the street being got round by two straight lines of conduit meeting at an angle, where a manhole is placed, and not by forming a curve in the conduit. This concrete conduit is, when properly set, lined with cement, making a very smooth, neat, and watertight job. The cover of the conduit is usually formed by laying paving stones across the top, the joints of which are carefully made with cement, the ordinary paving stones of the footpath being laid on the top of them with a little packing between.

Manholes are required at frequent intervals, at the corners of streets, when the mains cross a road, at certain intervals when the conduit is straight, and usually where connection is made to a house. These manholes are simply square openings in the conduit fitted with an iron frame having a groove round the bottom of the inside, which is packed. Another iron frame fits into this, having a projecting rim at the bottom which falls into the packed groove in the outer frame and keeps the manhole practically watertight. The inside of the frame of the lid is filled with concrete like the G.P.O. manholes, so that to an unobservant person they are hardly distinguishable. It is found that no water to speak of gets into these conduits, and if it does it is of such a moderate quantity that it can be baled out at intervals without difficulty. When the conduit is on a long incline and water tends to accumulate at the bottom, Messrs. Crompton and Co. place a small sump at the side of the manhole, in which the water collects. They state that in their whole system of mains at Kensington, there is only one place where the water continually collects, and here it simply requires a few quarts to be baled out once a week. The conduit being usually under the footpath, while the gas and water mains are in the roadway, only the local connections to the houses are come across as a rule. When these interfere with the line of the conduit, they of course have to be diverted either under or over it, but this with the small pipes is not a difficult matter.

There are, of course, a number of places, such as street crossings, &c., where it is impossible, from want of space and other reasons, to build this conduit; and here Mr. Crompton makes use of 1½in. screw-jointed iron pipes, as many separate pipes being run as he proposes to put lines of conductors in his conduit. Carefully-insulated cables are then drawn through these tubes and joined to the conductors at either end.

We now come to the way the mains are run in these conduits. At convenient distances stout oak cross-bars are fixed across the conduit at a short distance from the bottom, as shown in Figs. 6 and 7, the first of which shows a vertical section of the conduit, the second a horizontal view looking from above. These oak bars have holes bored in them forming sockets, into which drop the lower projecting portion of the glass insulators shown in the figure. Each glass insulator is thus kept firmly upright and in its place, but can easily be withdrawn and another one substituted if necessary. It will be noticed that the insulators have a very large insulating surface, which is further improved by the insulator being carefully dried and dipped in copal varnish before it is used.

The bare copper strip which is now run on these insulators is usually about 1in. broad by ¼in. thick, and can be got from the makers in lengths of some 700ft. By experiment, Mr. Crompton finds that it is quite easy to run this strip in the conduits with a distance between the insulating supports of

Digitized by Google

from 48ft. to 70ft., when proper means are used for straining the strip taut at intervals. With this distance between the supports it is easy to fix a manhole at each of them, so that the strip can be guided into its proper place by hand. The groove in the insulator is deep enough to take two or three strips one on the top of the other, but in such a case where several strips are required, it is found more convenient to pull in two or three new strips at the same time, than to pull another strip over the top of existing ones.

The method of straining the strips will be readily seen from the figures. Fig. 8 shows a side view of the strainer. Two oak bars are fixed one above the other across the conduit, and

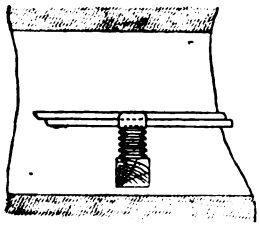

Fig. 6.—Crompton System. Method of Running the Conductors in the Conduit. Vertical Section.

in these glass insulators are fixed. Fitting on the top of these insulators is a bronze bridge with a slot through the centre and two tightening screws. The strip or strips are carried through this slot and strained tight by a special tool made for the purpose. While thus strained taut the tightening screws in the bridge are screwed down on the top of the strip, holding it firmly in its place. Fig. 9 shows a horizontal view of a man-

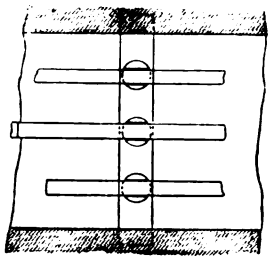

Fig. 7.—Crompton System. Method of Running the Conductors in the Conduit. Plan.

hole with three lines of mains coming into it and held by bridges. One strip is fastened to another or a cable running under a roadway to a strip by strong clamps without the use of solder.

The house connections from the conduit are usually made by means of indiarubber-covered wires laid in 1½in. gaspipe, and clamped to the bare main which runs past. A manhole

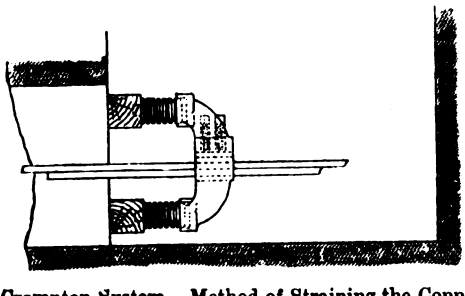

Fig. 8.—Crompton System. Method of Straining the Copper Strips. Side View.

for making this connection and getting at it is placed opposite the party wall of every other house, so that the house can be got at from the same manhole.

In some places it may be inconvenient in a conduit to use fixed insulators, or it may be advisable to substitute good-sized iron pipes for the conduit. To meet such cases Mr. Crompton has devised a special form of carriage insulator mounted on an insulated trolley running on wheels, so that the conductors, being fixed to the first trolley, can be drawn into the conduit or pipe, and additional trolleys be added as the conductors are pulled along at the distance requisite to keep them from touching the bottom or sides. Such a system does not require man-

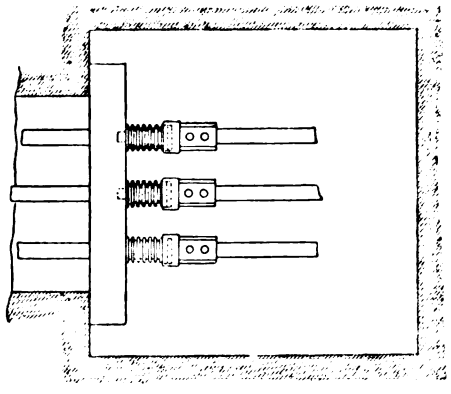

Fig. 9.—Crompton System. Horizontal View of Manhole with Three Lines of Mains coming into it.

holes over the insulators, and of course the conductors are easily withdrawn at any time. The two figures, Nos. 10 and 11, show a side and end view of the trolley as arranged for use in a square conduit. Its action will readily be seen. At each

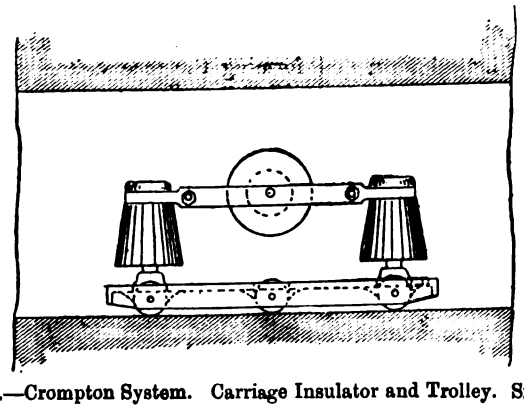

Fig. 10.—Crompton System. Carriage Insulator and Trolley. Side View.

end of the trolley are insulators. To the necks of each pair of these longitudinally a metal bridge is clamped. The bridge carries a deeply-flanged roller in its centre, in which the strip or strips lie. When used with pipes the trolley wheels are set at an angle, and a very ingenious arrangement has been devised for getting the trolleys to carry the strip properly round a gentle curve.

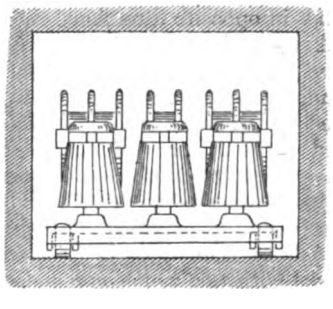

Fig. 11.—Crompton System. Carriage Insulator and Trolley. End View

As regards the insulating qualities of this system, they are certainly ample. Even when very damp the leakage over the surface of the insulators is very small and of a perfectly harmless character. The weakest point is where a cable is joined to a strip, but by arranging the junction properly, and carefully treating the end of the cable, the chances of any serious leakage are practically *nil*.

Underground Wires in Paris.

Le Genie Civil, in describing the electric light plant at the Halles in Paris, gives an account of the methods used in laying the wires under ground, from which we condense the following description:—The Municipal Council authorised the use of the sewers, but in spite of this the engineers have preferred to build special conduits. The cables, therefore, have been placed under the sidewalks in conduits of the form shown in Fig. 12, made of cement and 10·23 × 11·80in. in size. Wooden supports furnished with glass holders, which carry the cables, are placed at distances of 4·92ft. apart. These wooden supports slide freely in grooves made in the conduit, and thus form a method of suspension easily accessible for repairs. In crossing the streets, where the soil is very damp and permeable, cables are sunk one meter below the surface.

For the circuit at low tension the cables are made as follows: The wires are twisted together and covered with a layer of pure rubber; then with a layer of mixed rubber at least 2mm. (0·08in.), and finally by two bands of cotton impregnated with rubber. The whole cable is vulcanised in a compact mass, and is then protected by an outer covering of hemp soaked in rosin or tar.

For the high-tension circuit, on account of the narrowness of the sidewalk in certain streets, it was necessary to use, for a short distance, the sewers, and in order to avoid any disturbance of the telegraph and telephone wires on these sections, use was made of concentric cables. These cables were thus formed: A core of 19 copper wires of 2mm. (0·08in.), giving a section of 60 sq. mm. (9·3 sq. in.); the wires outside were covered by two layers of pure rubber 1mm. (0·04in.) in thickness, and then by several layers of vulcanised fibre wound in different directions; outside of this was a series of copper wires rolled in helical form and forming the second circuit, having the same total section as the core. These were covered in

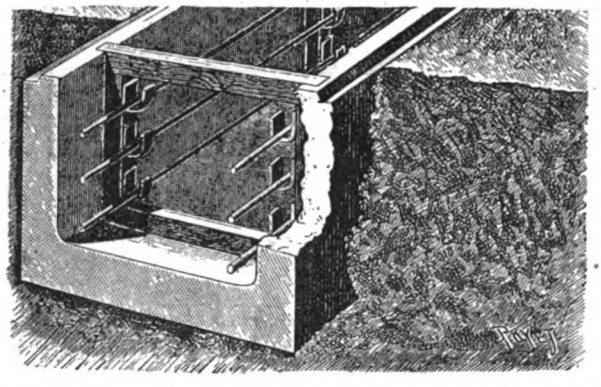

Fig. 12.—Conduit employed in connection with the Municipal Station at the Halles Centrales, Paris.

turn, first by two layers of pure rubber, then by several layers of vulcanised rubber 3mm. (0·12in.) thick, then by two vulcanised bands wound in opposite directions, then by hemp 3mm. (0·12in.) in thickness and saturated by a resinous composition, and then by two bands of vulcanised cotton. The whole was enclosed in a leaden pipe 2·5mm. (0·10in.) in thickness, which again was covered by twisted cord. This cable rests on wooden supports fastened in the masonry of the sewer.

For the ordinary high-tension cables the conduits are similar to those for the low-tension cables described above. The degree of insulation was carefully provided for in the specifications. These cables rest on wooden supports injected with sulphate of copper and covered with tar, which rest on porcelain insulators in the cement conduits. At the crossings of the streets the conduits are arranged as mentioned above.

The total length of 2,952ft. of concentric cables in the sewers and 19,024ft. of the ordinary cables was put down at a cost of about £3,000. The current furnished from the light station is sent out under a pressure of 2,400 volts. As it is furnished to each user under a tension of 100 volts, it is necessary to use transformers between the main circuits and each side connection.

(To be continued.)

THE THOMSON-HOUSTON ARC LIGHT SWITCHBOARD FOR CENTRAL STATIONS.

Of all the appliances used in the operation of arc light machines, says the *Electrical World*, from whom we take the following particulars, there is nothing of greater importance than a well-designed switchboard. There are but few central lighting stations in which commercial and street lights are not operated, making it necessary, for convenience and economy, to place two or more circuits in series on one dynamo, to transfer circuits from one machine to another, and to make such combinations of dynamos and circuits as local conditions render necessary. It is most desirable that there should be no extinguishment of the lights while these changes are being made, and that the construction of the board be such as to insure the operator against receiving a shock while so doing. The switchboard here shown (Figs. 1 and 2) meets these requirements, is incombustible, and is of such construction that additions can be readily made without necessitating any changes in the part of the board having the circuits already in position.

As will be seen from the illustrations, the board is made of two rectangular slate slabs, placed about five inches apart, into which are fitted rows of metal bushings, those arranged

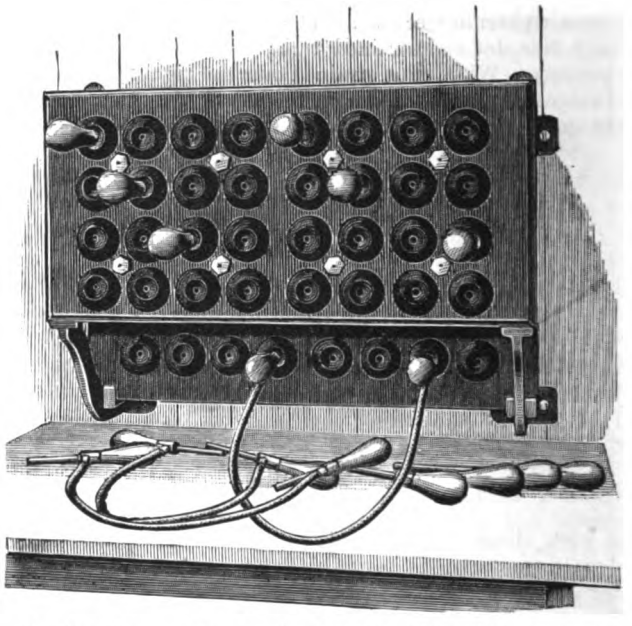

Fig. 1.—Thomson-Houston Arc Light Switchboard (front view).

horizontally on the front board being connected to the dynamos, while the vertical rows on the back are connected to each other and the circuits. On the back there is one more row of bushings than on the front, this extra row being used to connect one circuit with another by means of the transfer cables and plugs.

The switchboard is made for four and six circuits, and is so arranged that additions may be easily made by which the number of dynamos and circuits will be a multiple of four and six. The positive and negative terminals of the dynamos are connected to the left and right side, respectively, of the front board, and the circuits on the rear board in a like manner, the left being positive and the right negative, the bushings for the dynamos being numbered vertically 1, 2, 3, 4, while those for the circuits are numbered horizontally 1, 2, 3, 4. To connect a machine to a circuit the plugs are pushed through the holes on both positive and negative sides of the board corresponding to the dynamo and circuit desired.

To connect any two circuits in series on one dynamo before the machine is started, the plugs are pushed through the holes corresponding to positive of one machine and one circuit, and then by means of the transfer cable and plugs at the bottom of the rear board the negative of this same circuit is connected

Digitized by Google

with the positive of the second circuit which it is desired to place in series with the first, the final connection being made by pushing the plug through the hole corresponding to the negative of the second dynamo and negative of second circuit.

To transfer circuits from one dynamo to another when the machines are in operation, without disturbing the lights—as, for instance, transferring circuit No. 1 from No. 1 to No. 2 dynamo—No. 1 dynamo is connected to No. 2 circuit by the plug, and No. 2 dynamo to No. 1 circuit. The circuit can then be broken between the dynamos and circuits No. 1 and No. 2, permitting No. 1 dynamo to be shut down, and the positive of circuit No. 2 connected to negative of circuit No. 1 by means of the transfer cables and plugs.

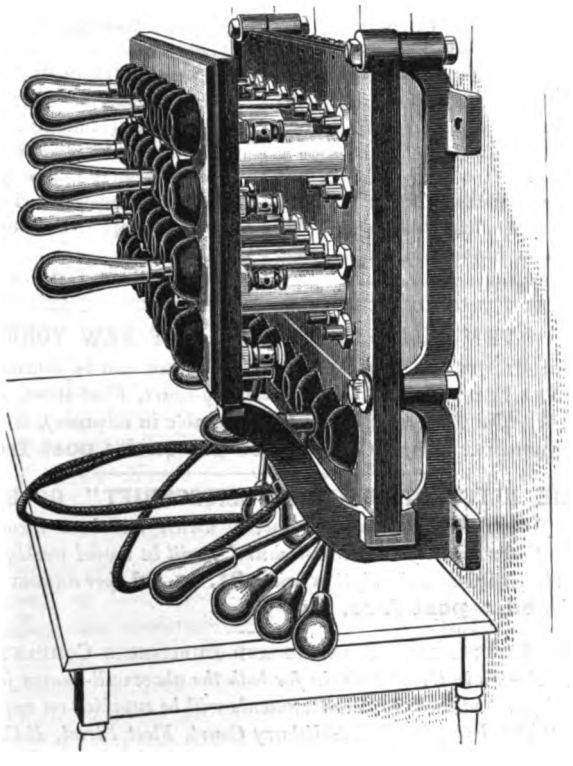

Fig. 2.—Thomson-Houston Arc Light Switchboard (side view).

The wall space required for a four-circuit board is 19 × 25in., and that for a six-circuit board 24 × 35in.

THE MOLECULAR AND ASSOCIATED CHANGES OCCURRING IN IRON AND STEEL WHEN HEATED AND COOLED.

BY DR. G. GORE, F.R.S.

Before the immediate interest of Dr. Hopkinson's Presidential Address on Magnetism has ceased, I beg leave to make the following remarks on one of the essential points of the address, viz., the molecular and other associated changes which occur in iron and steel during heating to redness and subsequent cooling.

In the address, the experiments of Prof. Barrett (*Phil. Mag.*, December, 1873) and the later ones of M. Osmond were very suitably mentioned, whilst earlier ones respecting the very thing, viz., the molecular and associated changes, of which the President was speaking, were omitted. These experiments were described in a Paper on "A Momentary Molecular Change in Iron Wire" (*Royal Soc. Proc*, January, 1869, Vol. XVII., p. 260), "The Development of Electric Currents by Magnetism and Heat" (*ibid*, p. 265), and "Molecular Movements and Magnetic Changes in Iron, &c., at Different Temperatures" (*Phil. Mag.*, September, 1869, p. 170).

In the latter of these papers (p. 172) was, I believe, first published the fact of the sudden molecular change and alteration of length which occur in iron at a red heat, and was first recorded the connection of these changes with the chief magnetic one in iron and steel, and the occurrence of smaller changes of the same kind in those substances. The happening of this molecular change during cooling, as well as during heating, was mentioned (*ibid*, p. 172), and similar small molecular alterations in nickel during heating and cooling were similarly made known (*ibid*, 175-176).

These earlier simple experiments, unaccompanied by precise measurements, appear to have originated a number of allied researches by various investigators. It was by repeating one of these experiments, with the aid of an apparatus furnished by me, that Prof. Barrett was led to discover the phenomenon of recalescence of iron (*ibid*, December, 1873, p. 472). In the Paper on "Molecular Movements and Magnetic Changes in Iron, &c., at Different Temperatures" (*ibid*, September, 1869, p. 177), it had been already stated, as an inference from the results of the experiments, that "simply by heating a bar of iron to redness a whole series of changes occur in its molecular structure, its magnetism, its dimensions, its cohesive power, its specific heat, its thermo-electric capacity, and its electric conducting power." The change of specific heat was subsequently experimentally proved by Prof. Barrett, and each of the other statements has, I believe, been since similarly demonstrated by a variety of researches made by different investigators, including Dr. J. Hopkinson.

As these earlier original experimental facts appear to me to constitute an essential basis of the subsequent researches, and without them no measurements respecting them nor application of them to practical purposes could be made, some notice of them in connection with one of the essential points of the address, viz., the molecular and associated changes, appears to me desirable. The accidental association of my name with those experiments is quite a secondary matter.

MEETINGS OF SCIENTIFIC SOCIETIES, &c.

For Foreign Parts and Colonies:—	s. d.	s. d.	s. d.
Within Postal Union	6 6	12 6	24 0
Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7 6	14 6	28 0
The rates for the United Kingdom remain as follows:—	5 0	10 0	19 6

TO ADVERTISERS.

"The Electrician" *offers exceptional advantages to Advertisers.* **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to the office.

Trade Advertisements *intended for the current issue must be handed in not later than First Post on Thursday morning.*

Small Prepaid Advertisements *(for Rates see page xv.) are accepted up to 4:30 p.m. on Thursday.*

TECHNICAL PRINTING.

"The Electrician" Printing and Publishing Company (Limited) *beg to inform Electricians, Electric Light Engineers, &c., that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

"THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK.

Royal 8vo.

Early in each year is issued "The Electrician" Electrical Trades' Directory and Handbook. *The Directory was established in 1883, and the 1889 Edition consisted of more than 600 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with popularly-written Biographical Notices of the leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

The issue for 1890, which is still further enlarged and improved (making 850 pages), is NOW READY. Orders should be forwarded at once to the Publishing Offices, Salisbury-court, Fleet-street, London, E.C.

CONTENTS OF THE CURRENT NUMBER.

"THE ELECTRICAL WORLD" OF NEW YORK.

"The Electrical World" of New York *can be obtained from* "The Electrician" *Office, Salisbury-court, Fleet-street, London, E.C. The Rate of Subscription (payable in advance), is* **£1 1s.** *per annum. Single Copies* **price 6d. each; post free, 8d.**

"THE ELECTROTECHNISCHE-ZEITSCHRIFT" OF BERLIN.

In future the above journal (with which has been incorporated "The Centralblatt für Electrotechnik") will be issued weekly instead of fortnightly, the subscription being **£1. 4s. 6d.** *per annum. Single Copies* **6d.; post free, 7½d.**

"The Electrician" Printing and Publishing Company, Ltd., *are Agents in Great Britain for both the above well-known journals, and particulars as to Advertisements will be supplied on application to "The Publisher," 1, Salisbury Court, Fleet Street, E.C.*

THE INSTITUTION OF ELECTRICAL ENGINEERS.

Notwithstanding many predictions to the contrary, the growing prosperity of the Institution of Electrical Engineers has been latterly so marked as to call forth the congratulations of its best friends, and to almost silence its severest critics. The little band of telegraph engineers who met in 1872 to found their Society, and of whom Major-General Webber is now the sole survivor, have seen the small seed which they planted and fostered with such assiduous care grow and expand until it has become a flourishing tree. Under its new style and title it is becoming even more popular than in the days when it modestly styled itself the Society of Telegraph Engineers, and its membership is growing by leaps and bounds. In 1888, whilst still nominally a society of telegraph engineers, it added 168 to its already large membership. In 1889, its first year after the reorganisation on a wider basis, it admitted no fewer than 183 new names, and the rush of applications for admission continues. At every meeting from 20 to 30 names are submitted to the ballot, after having passed the preliminary step of consideration by the Council. It is clear that, in the eyes of the electrical profession—and under this term we would of course include the manufacturers and traders in the electrical industries—the Institution has justified its existence, and has proved itself to be a body to which it is an honour to belong. All this means that the Institution is being worked in a way that commands success and respect.

Digitized by Google

The excellence of the Papers read at its meetings, the quality and freedom of the discussions upon them, the promptitude and fulness of the reports issued to the members, not only attract attentive audiences at the meetings but proclaim the advantages of membership. Add to these things the increasing recognition given to the Institution, its influence in the scientific and professional world, the fact that it is consulted from time to time by such bodies as the Board of Trade upon questions that arise affecting the electrical industries, and it becomes evident that the INSTITUTION OF ELECTRICAL ENGINEERS is an association of great and rapidly-increasing power. Other electrical societies, such as the American Institute of Electrical Engineers, the Elektrotechnische Verein, in Berlin, and the Société Internationale des Électriciens, in Paris, may be in a sense equally flourishing. But not one of them commands to-day the influence of our own Institution. In none of them are the proceedings of the same high average order; at the meetings of none of them is it possible to gather together for debate so large a number of distinguished electricians.

Satisfactory as such a position may be, the very magnitude of the present success evokes reflections of another nature than mere congratulation. Can so rapid a growth be healthy? Is it not possible, unless some check is placed upon the present rush for membership, that there may come a serious reaction? Is the Council of the Institution alive to the possible dangers in store from so rapid an influx? Are the persons who are being drafted in by twenties and thirties deserving of membership, or will not some of them weaken the Institution rather than strengthen it? These are questions which may well be asked at the present time.

Consider the advantages of admission. Every member, whether his grade be that of "Student," "Associate," "Foreign Member," or full "Member," has the privilege not only of attending the meetings and introducing his friends, but of receiving the published volumes of the *Journal* of proceedings, the intrinsic value of these being in itself quite equal to the actual sum paid by the mere "Student" member. The Associate or the full member is, moreover, entitled to signify to the world by certain mysterious initials after his name that he belongs to the Institution. Doubtless a not very small percentage of the candidates for admission have an eye to the commercial value of this fact. The half-instructed electrician who desires to pose as a full-fledged electrical engineer aspires to the unassailable dignity of Associate. The enterprising civil engineer, who knows all about gas and water and highways, and sees that vestries and corporations require electrical advisers, also aspires to membership in the one professional body that will entitle him in the eyes of the world to pose as an electrical authority. Far be it from us to decry as unworthy the motives of all candidates for membership: there are degrees of worthiness, and few men are so constituted that their desires in joining a society are absolutely disinterested. But knowing that a few, at least, of the candidates who are rushing into the Institution possess qualifications of an extremely limited kind, it behoves those who have the interests of the Institution at heart to watch the ballot boxes very narrowly lest something of a catastrophe occur. In every society, sooner or later, there arises a crisis of the kind we desire to stave off from our own Institution. Fifteen years ago the Chemical Society went through such a crisis: when after a rush of popularity, during which admission to the fellowship of that society had been granted to a number of persons of very miscellaneous qualification, a small but determined knot of real chemists determined, by unsparing and almost indiscriminate use of the black ball, to reject every candidate who did not come up to their standard of qualification. Through a similar crisis, if we are not mistaken, the Institute of Actuaries is now passing. It is the price—we had almost said the penalty—of success.

All true friends of the Institution must earnestly desire that no such crisis fall upon their organisation to cripple its usefulness, and paralyze its energies by internal bickerings. And the only way to obviate such an undesirable occurrence is to foresee its possibility and to guard against it. Happily our Institution has grades in its membership, and it is always possible to propose for admission to the lower grade of associateship one who, though desirable in that capacity, is not really eligible to be accepted as a full Member. The one important question to be asked on every proposal for membership (assuming always the personal worthiness and integrity of the candidate) is this: Is he really an electrical engineer? If he is only an electrician and not an engineer, or if he is only an engineer and not an electrician, then he ought to be contented with becoming an associate, and ought not to be admitted to the full membership. Of course there are exceptions: there are distinguished engineers—men at the summit of their profession—whose accession to membership in any scientific society does at least as much honour to the society as the society could possibly do to them. But the Institution and its Council cannot be too particular to ensure that, save for special distinction, none are admitted as members of the INSTITUTION OF ELECTRICAL ENGINEERS who are not truly engineers and truly electricians. We have heard it suggested that the power of transferring persons already in the class of "Associate" to the class of "Member," now vested in the Council, should be henceforth vested in the Institution at large, and that all transfers, like all original proposals for membership, should go through the ordeal of the ballot. This is a step of doubtful wisdom: a better plan would be for the Council itself to vote such transfers by ballot, instead of by a mere show of hands at the Council-table. For, in truth, the machinery of the ballot box in the Institution is even now unwieldy, and, if not carefully watched, may be abused. Our warning will not have been in vain if it helps the professional body that watches over the interests of our craft, and with which we all are proud to be associated, in however humble a capacity, to steer clear of one of those quicksands which so often underlie the flood-tide of prosperity.

REVIEWS.

Absolute Measurements in Electricity and Magnetism. By ANDREW GRAY, M.A., F.R.S.E. Second Edition. (Macmillan and Co.)

This is a revised and greatly enlarged edition of the works under the same title, published in 1884, and, unfortunately, long since out of print. It is simpler and less comprehensive than the larger treatise by the same author on "The Theory and Practice of Absolute Measurements in Electricity and Magnetism." It is of a more practical nature, and is designed for the use of students who are not sufficiently equipped mathematically to follow the larger work. The purpose of the book is not so well indicated in its title as in the introductory chapter, wherein it is stated that the main object of the author is to give an account, both theoretical and practical, of the methods of measurement of current and potential in absolute units, and of the application of these to the graduation of instruments for use in practical electrical work.

The second chapter deals very fully with the determination in absolute measure of the horizontal component of the earth's magnetism. The apparatus described is exceedingly simple in character and trifling in cost. The student need have but very little manipulative skill in order to make for himself all that is necessary for carrying out the various experiments. The descriptions given are minute and practical, dimension,

Digitized by Google

and diagrams being supplied, as, for instance, with regard to the manufacture and setting up of the magnetometer and the deflecting magnets. Many sources of error in the measurement are noticed, and the necessary corrections are carefully discussed. We notice on page 28 that, owing to a slip in the formula for the moment of inertia, the equations (10), (11), and (12) are erroneous. The chapter concludes with a detailed description of actual experiments made by Mr. T. Gray to determine the value of H at Glasgow. Next to making experiments for himself, nothing more vividly brings home to the student the reality and simplicity of physical science than the numerical description of actual experiments. This method of teaching might with advantage be much more frequently followed in text books than it is. It is a great pity that Prof. Gray resorts to the use of such ancient expressions as "blue pole" and "red pole." We do not think there is any liability to confusion owing to the fact that the magnetism of the north pole of a magnet is of the opposite kind to that of the north pole of the earth, and, even if there is, matters are not improved by arbitrarily colouring the poles. It would probably be better entirely to cease to talk about poles, and simply refer to the number and direction of the lines of force produced by the magnet. As far as experiment shows, lines of force have a far greater claim to real existence than the imaginary magnetic matter which is assumed to be concentrated near the two points called poles.

The following four chapters deal with the absolute units of magnetic pole, magnetic field, electric current, potential, and resistance. The theoretical and practical considerations which have to be taken into account in the construction of a standard galvanometer are discussed rather fully, and some space is devoted to the theoretical determination of the distribution of current and potentials in derived circuits and in networks of conductors. A long and important chapter follows, describing standard electrical measuring instruments and the methods of graduating them. Mr. Gray's experience in the Glasgow laboratory is, of course, such as to specially qualify him to give authoritative descriptions of all Sir William Thomson's instruments, whether of the laboratory or engineering types. The current balances, the White form of quadrant electrometer, and the electrostatic voltmeters, including the new multicellular ones, are treated at length; and the author then proceeds to discuss the calibration of current meters by the copper deposit method, which has been developed into a satisfactory one by Mr. Thomas Gray's experiments made in Sir William Thomson's laboratory. A good abstract of these experiments is given, the copper voltameters used being illustrated and described. The great importance in modern practice of having properly standardised instruments will render this chapter exceedingly valuable to many readers. The lengthy chapter which follows on the measurement of resistance is much the same as the corresponding one in the author's larger work. The measurement of electrical energy, and efficiency, with especial reference to alternating current circuits, are the next subjects discussed. The theory of alternating current machines is given, as is also an account of Dr. Hopkinson's theory of the working of alternators in series and in parallel. The analytical method is retained, although in our opinion the same results are obtained in a simpler and clearer manner by graphical processes. It is, however, an advance to have the subject introduced into a text book. The importance of impedance and self-induction in connection with alternating current circuits is so great, that the omission of any method of measuring these quantities in a book entitled "Absolute Measurements" is certainly one which should be remedied when a new edition is called for. Methods are given in the next chapter for the measurement of intense magnetic fields, such as are met with in dynamo machines; and the concluding chapter deals with the theory of the dimensions of the units of physical quantities. The author adopts Prof. Rücker's suggestion that the unknown dimensions of specific inductive capacity and magnetic permeability should be indicated instead of being ignored, and in consequence the difference between the electro-magnetic and the electrostatic units, and the transfer from one to the other is, for the first time, made clear to the student. Some useful tables bring the book to a close.

THE PHYSICAL SOCIETY.

At the meeting of this Society held on January 17th, Prof. S. P. Thompson's paper on "Electric Splashes," of which we published an abstract last week, was followed by a Paper

"On Galvanometers,"

by Messrs. W. E. Ayrton, T. Mather, and W. E. Sumpner, which was read by Professor Ayrton, and which will be discussed this afternoon (Friday, February 7th).

The Professor observed that when fitting up the Electrical Laboratories of the Central Institution in Exhibition-road, a large number of galvanometers were obtained, some of which were of novel types specially constructed.

These instruments were subjected to a number of comparative tests by Messrs. Mather and Sumpner, and students working under their direction; and he was of opinion that a record of the results obtained would be of value, as affording data for the selection of instruments most suitable for the objects in view, as well as offering suggestions for future improvements in the manufacture of galvanometers.

The first question which arose was whether it was always advisable that sensitive galvanometers should be astatic. Prof. Gray, in his treatise on Absolute Measurements in Electricity and Magnetism, maintains that it is not, observing that while sensibility is sometimes obtained by the astatic construction, it is rarely necessary, and such instruments give more trouble than single-needle galvanometers. The Professor observed that Mr. Gray's opinion carried special weight, as it might be taken as practically expressing Sir William Thomson's views on the subject. Sir William had, indeed, himself expressed the opinion that the best method was to employ a single needle and weaken the magnetic field as far as requisite by means of controlling magnets. Theoretically there was no limit to the sensibility obtainable in this manner, but the practicable limit

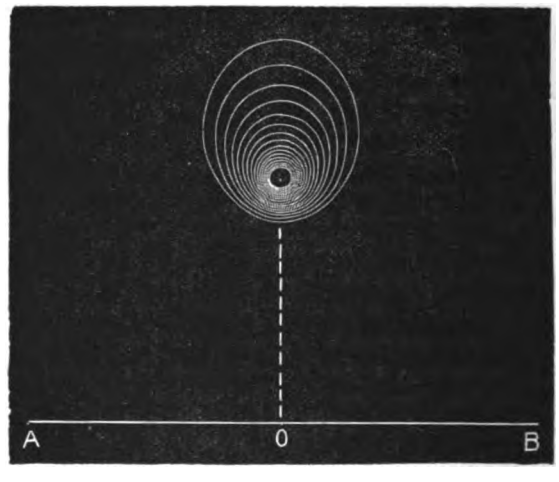

Fig. 1.

due to instability was reached sooner with non-astatic galvanometers than with astatic ones. Another important advantage of astatic over non-astatic instruments was their much greater freedom from external magnetic disturbance, and the resulting increased stability of the zero point. These were very important advantages in favour of the astatic construction, and in view of these facts the authors could not admit that astatic instruments were more troublesome to work with than non-astatic ones—the reverse being in their opinion the truth, on account of the comparative freedom from external disturbance.

It was then pointed out that in the ordinary method of constructing astatic galvanometers some of the most valuable portion of the coil was cut away to provide a space for the magnetic needle and mirror. Mr. Mudford, while a student at the City Guilds Institute, had suggested that the needle only should be placed within the coils and the mirror outside, or when four coils were employed, between the two pairs. This suggestion was submitted to Sir William Thomson, who considered it a good one, and some instruments constructed in this manner were exhibited at the meeting, and it was stated that they had proved extremely satisfactory. When this arrangement was adopted it was not necessary to leave even a small gap right through the coils, as was required when the mirror was in the usual position, to provide a passage for the ray of light.

It was next pointed out that the space left unwound within the coil should be larger than was required simply to allow the needle to turn, for if the winding was carried too close to the needle the effect on the latter of the innermost coils would be opposed to that of the rest of the coil. This is easily seen from Fig. 1, which

Digitized by Google

shows a section of the lines of force, and of the equipotential surfaces, due to a current in a circular conductor, the cross-section of which is shown by the small circle in the centre, having its centre at the point O, and its plane perpendicular to the line A B. The equipotential surfaces are oblate surfaces of revolution having the line A B as their common axis. (*See* Maxwell's "Electricity and Magnetism," Vol. II., Plate XVIII., and Art. 702.) The space to be left unwound was deduced graphically from this figure by drawing the curve passing through the points on the lines of force at which the tangent is perpendicular to the axis.

Taking a point $x\ y$ on this curve, and supposing the radius of the coil to be unity, the co-ordinates $x^1\ y^1$ of a point on the curve representing a section of the critical surface within which the winding should not be continued will be given by

$$x^1 = \frac{x}{y}, \quad y^1 = \frac{1}{y}.$$

A section of the critical surface obtained in this way for one of the coils experimented with is shown in Fig. 2. The longer axis

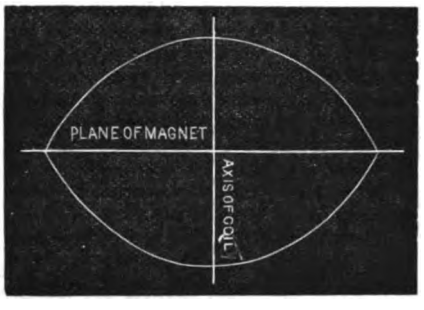

FIG. 2.

of the spheroidal figure was found to be about ·72 of the length of the needle. Mr. Mather had suggested that instead of leaving this space unwound it would be preferable to have it wound in the opposite direction to the rest of the coil, so that no portion of the space in the neighbourhood of the needle should be magnetically useless.

Details as to the methods of supporting the coils were then discussed, and the importance of fitting them in boxes mounted on hinges or otherwise, so as to be readily removable, was pointed out. A galvanometer devised for teaching purposes, and provided with variable damping arrangement, was described, in which the damping is effected by enclosing the mirror in a glass cell whose sides can be caused to approach or recede by turning a milled head outside the instrument. This arrangement enables the damping to be varied between wide limits, and its effect on the swing produced by a given discharge can be determined. The instrument is also serviceable both as an ordinary damped galvanometer or as a fairly ballistic one.

FIG. 3.

In Elliott's old pattern of galvanometer, in addition to the portion of the coils left unwound to admit the light to the mirror, a second portion was similarly left on the lower set of coils to admit the damper, a most objectionable arrangement, and one which did not appear to have any reason whatever in its favour. The method of damping preferred by the authors was to attach the mirror to a long vertical strip of mica or aluminium, across the upper and lower ends of which the magnets were fixed, as shown in Fig. 3.

With this arrangement, with a galvanometer having a vibration period of seven seconds or upwards, the needle did not visibly pass through the zero, or was absolutely dead-beat, and even with one having a very short period it would not do so more than twice.

In measuring quantities of electricity by the first swing of a galvanometer needle, a correction has usually to be introduced for damping. This correcting factor is simple enough when the damping is small, but becomes more complex as the damping increases, and to facilitate the calculations a table of values of the factor for various values of λ (the logarithmic decrement) had been calculated. From this it appeared that for values of λ less than 0·5, no sensible error would arise from replacing the factor by its first approximation, $1 + \frac{1}{2}\lambda$.

Improvements in the methods of insulating the coils and terminals of galvanometers intended to be used for insulation tests were then discussed. The common plan of allowing the bare wires to lie along the under surface of the ebonite base of the instrument was strongly objected to, and Prof. Ayrton stated that when he was engaged at Messrs. Siemens' works, in 1872, they always had to light a gas jet the first thing in the morning to dry the ebonite base of the galvanometer they were going to use, and thus prevent as far as possible the leakage across the ebonite between the bare wires and the terminals attached to the base. The coils and terminals should always be supported by paraffined ebonite pillars contained within glass cases and kept dry by means of sulphuric acid.

A special form of instrument for high insulation work was exhibited, in which the copper resistance of the coils is nearly 400,000 ohms, and the shortest path along which surface leakage can take place from the coils or from the terminals to the base of the instrument is between 30 and 40in. of ebonite in an atmosphere artificially dried by sulphuric acid. This is attained by supporting the coils from two corrugated ebonite rods, which hang from a brass ring carried on the top of three corrugated pillars fixed to the base plate. The instrument was constructed to drawing by Messrs. Nalder Brothers, but the method of supporting the coils was suggested by Messrs. Eidsforth and Mudford.

With reference to the proportionality of deflection to current in reflecting galvanometers, it was pointed out that ordinary reflecting galvanometers may differ more than one per cent. within the limits of the scale, hence showing the necessity for calibration when any approach to accuracy is desired. Galvanometers of the D'Arsonval type sometimes differ from proportionality more than the one above referred to, but by fitting such instruments with curved pole-pieces, and allowing the coil to hang freely from the top suspension, a proportionality true to less than 0·15 per cent. has been attained over a scale about 30in. long. The following abstract of tests made indicates the amount of error which may arise :—

Coming to the question of sensitiveness, the importance of keeping the wire as close as possible to the magnets was brought prominently forward, as well as the necessity of reducing the "figure of merit" of various instruments to the same standard in comparing their sensibilities. A satisfactory standard of comparison is, however, not easy to determine. The sensibility in use of any instrument is made up of many factors, some of which arise from the skill of the experimenter himself. It is also desirable to give the data in such a way that the influence of each factor can be separately determined. The authors have therefore endeavoured to distinguish, as far as possible, the three chief factors of the sensibility of reflecting galvanometers, viz., the arrangement and winding of the coils, the construction of the magnetic system, and the optical method of magnifying the angular deflection produced. With the same view the question of the susceptibility of various galvanometers to outside magnetic disturbances has been considered separately, since, first, the electrical qualities of the instrument are not altered by such disturbances; and, secondly, their influence is dependent, not only on the kind of instrument, but on the place of test. Galvanometers have therefore been classified in four divisions, according to their relative sensitiveness to slight variations in the controlling field. The strength of the controlling field is supposed to be so adjusted that the returning moment arising from twisting the suspended parts through a unit angle from the equilibrium position is constant. The four classes, arranged in order of decreasing susceptibility, then comprise: non-astatic galvanometers working in a weak field and with strongly magnetised needles; non-astatic instruments working in a strong field and with needles not so strongly magnetised; astatic galvanometers working in a fairly strong field; and, lastly, galvanometers of the D'Arsonval type working in an extremely strong field.

The optical sensitiveness of a galvanometer is dependent on many considerations which have no connection with the instrument itself.

EXPLANATION OF TABLE.

r = resistance in ohms.
M = millimetres deflection per micro-ampere when the period is 10 seconds and the scale is placed as in the actual use of the instrument.
S = swing produced per microcoulomb under the same conditions as for D.
D = deflection in divisions per micro-ampere when the period is 10 seconds and the scale distance is equal to 2,000 scale divisions.
I = moment of inertia of suspended parts in C.G.S. units (only approximate).
V = volume in cubic centimetres occupied by the convolutions of wire (only approximate).
* These numbers are calculated from the corresponding values of D.
† The constants of these instruments were kindly supplied by the makers.
‡ These instruments were tested after being in use for some years, the needles not being re-magnetised.
‖ Large.

Thus the goodness of the mirror, the distance of the scale, &c., are important factors. The authors have hence contented themselves with giving the number of scale divisions per micro-ampere or per micro-coulomb, assuming the scale to be placed at a distance from the mirror equal to 2,000 scale divisions. As the scale distance most generally used is a metre, and as the scale divisions are frequently in half-millimetres, the conditions assumed are often fulfilled in practice. The sensibilities for a steady current, and for a discharge are thus directly expressed in angular measure, irrespective of optical magnification. The sensibility at the usual scale distance employed with each instrument is, however, given as a guide, for it must be remembered, in comparing sensibilities for the same periodic time of vibration, that two instruments may have very different sensibilities, although identical in all respects save the moment of inertia of the suspended parts, and these may differ because a larger and heavier mirror has been attached in order to employ a longer scale distance.

An important and difficult question is whether the factor of merit of a galvanometer should be given under the condition of constant period, or of constant controlling moment, or of constant controlling field. The first is the easiest to obtain and to calculate from, and is most readily understood. In the table of data of the many instruments tested, only an abstract of which is here published, two columns have therefore been reserved for the values of D and S, which respectively denote the deflection per micro-ampere and the swing per micro-coulomb, each in scale divisions, when the period is 10 seconds and the scale distance is 2,000 scale divisions. The corresponding values at any other period T are of course $DT^2/100$ and $ST/10$. It is, however, unfair to judge the relative merit of two instruments by simply comparing their action when the period is 10 seconds in each case, for this period may be unsuitable for use with one or both of them. It is, moreover, not quite right to compare the values of D and S when the usual periods are employed, as these may not be all equally favourable to the instruments considered. The authors therefore determined to reduce the numbers to their corresponding values under the condition of constant controlling moment per unit angle. The alternative of constant controlling field was rejected because it is inapplicable to instruments of the D'Arsonval type. The stability of the zero of any instrument, however, depends on the controlling moment per unit angle, and the values of D and S (*see* Table) have therefore been multiplied respectively by I and $\sqrt{I}$ where I is the moment of inertia of the suspended parts in C.-G.-S. units. In this manner the numbers contained in columns 7 and 8, proportional to the sensibilities for constant controlling moment, have been obtained, and these, perhaps, give a fair comparison between the various instruments when the time required to take an observation is entirely unimportant. It should be borne in mind, however, that the period of instruments in which the moments of inertia of the suspended parts are large, such as Rosenthal, Gray, or ordinary D'Arsonval galvanometers, would be inconveniently long.

The influence of resistance has next to be considered. If two galvanometers differ only in the gauges of wire with which they are wound, and the convolutions are similarly distributed, then the sensibilities should be proportional to the number of turns. If, again, the thickness of the insulating covering bears a constant proportion to that of the wire, then the resistance of the coils would be proportional to the square of the number of turns, so that the values of $D/r^{\frac{1}{2}}$, $S/r^{\frac{1}{2}}$ would be constants for the same pattern of instrument, where D and S are the number of scale divisions per micro-ampere and micro-coulomb respectively, and r is the resistance of the galvanometer. The proportion in question, however, varies not only for coils of different resistances, but also in the same coil, for several different gauges are generally used in winding the various portions. To get some idea of the relation between resistance and sensibility the authors have made tests on galvanometers of the same pattern but of different resistances (the same magnetic system being used throughout), and have found that D and S vary approximately with the value of r raised to the power 2/5, *i.e.*, $D/r^{\frac{2}{5}}$ and $S/r^{\frac{2}{5}}$ are approximately constants for galvanometers of the same pattern. These quantities have, accordingly, been taken as the factors of merit of the galvanometers for constant period, and their values are given in the table (*see* cols. 10 and 11).

Another question to be considered is the factor of merit in connection with the volume of the coils. As this is important as regards the cost of high-resistance galvanometers, a separate column (5) is therefore given, showing the approximate volume in cubic centimetres occupied by the wire in each instrument, and other columns (14, 15, 16, 17) give the values obtained by dividing this quantity into the various factors of merit. The results of comparison in these latter columns are very interesting. It appears that galvanometers of the Rosenthal or Gray and the D'Arsonval types are by far the most sensitive in proportion to the volume of coil. The authors believe that the best way to make a very sensitive galvanometer with a movable magnetic system is to employ several small coils, instead of one or two large ones, and that the magnets should be horseshoe shaped, with the line joining the poles vertical, as in Professor Gray's

Digitized by Google

instrument, but modified so as to give a smaller moment of inertia.* Such a magnetic system can be made very delicately astatic, and the weakening of the magnets with time does not greatly influence the astaticism. The authors also conclude from their investigations that the most sensitive galvanometer of all would be one of the D'Arsonval type suitably modified. The poles of the magnet should be very close together, the coil should be very small, and no stationary iron core should be used inside the coil, as in the ordinary D'Arsonval galvanometer. The sensitiveness could be further increased by employing electro-magnets instead of permanent ones to produce the deflecting field.

Experiments have also been made on the co-efficients of self-induction of galvanometer coils, and a table of values is given in the Paper. From this it appears that a coil of ordinary size used in Thomson galvanometers has a co-efficient approximately equal, numerically, to one-thousandth of its resistance in ohms. If the coils of the instrument are in series and placed near each other, as in actual use, the co-efficient is increased by about half its former amount, owing to mutual induction; so that for Thomson galvanometers whose resistances vary between 1,000 and 10,000 ohms, the time constant is about 0·0015 second. Very high resistance instruments have a smaller time constant owing to the increasing importance of the insulating covering of the wires. The authors also discuss the possibility of judging the electrical qualities of galvanometer coils by measurements of their induction co-efficients.

The importance of having the magnets of galvanometers as strongly magnetised as possible is illustrated in a table showing the results of experiments made at the Central Institution. In many cases the sensibility of an instrument has been trebled (for the same periodic time of vibration) by simply re-magnetising the needles, and in one case the sensibility of an instrument had fallen to one-fifth of its original value by the weakening of the magnets with time and use. The experiments show that however carefully a galvanometer may be used, it is advisable to re-magnetise the magnets occasionally.

In view of Mr. Preece's remarks at the Institution of Electrical Engineers on January 23rd, on the deteriorating quality of magnet steel, it is of the first importance that for sensitive galvanometer needles only the very best quality obtainable should be employed.

Owing to the lateness of the hour the discussion on the Paper was postponed to the next meeting, which is to be held to-day (Friday).

THE ARON METER.

So far as we are aware, no independent report has, up to the present, been published in this country as to the degree of accuracy which any of the numerous types of electricity meters now coming into use may be expected to attain under conditions approximating those likely to obtain in practice. The following report of Mr. Gisbert Kapp to the General Electric Company, on the well-known Aron Meter (see *The Electrician*, February 8, 1889, p. 393), will therefore be of interest both to consumers and to the various electric supply companies:—

GENTLEMEN: I have subjected the Aron Meter which you supplied to a series of tests, extending over about 10 days, and now report to you on the results of these tests.

The meter consists of a pair of pendulum clocks, so geared together as to register the difference in their rates on a set of dials. One of the clocks has an ordinary pendulum, whilst the bob of the pendulum of the other clock consists of a fine wire solenoid, placed horizontally, and swinging within a fixed solenoid of much stouter wire, through which passes the supply current which is to be metered. The fine wire solenoid is connected in series with a resistance coil, and the two form a shunt to the supply leads. The connections are so arranged that there is attraction between the shunt solenoid and the main solenoid, and consequently acceleration of the electric as compared with the gravity pendulum: the difference in rate, which is registered on the dials, being very nearly proportional to the amount of energy passed through the meter in any given time. To find this energy, we have, therefore, to multiply the number registered on the dials by a coefficient, which must be determined for each meter by experiment, and which in an absolutely perfect meter should be a constant for all currents and pressures within the range of this instrument. I do not know any meter in which the coefficient is absolutely constant: it varies with the amount of current, and the amount of variation is an indication of the greater or less accuracy of the meter. To judge of the merits of a meter it is only necessary to determine the co-efficient for different currents and pressures, and to compare the coefficients with each other. The more nearly the coefficients agree, the greater is the degree of accuracy attained by the meter.

I have tested your Aron Meter at pressures varying between 130 and 95 volts, and with currents varying between 26 and 7 amperes, both direct and alternating. In addition, I have also made a prolonged test with a direct current of 0·65 ampere.

The meter is designed for a mean pressure of 100 volts, and a maximum current of 25 amperes. I found that the coefficient is practically unaffected by variations in pressure between the limits of 95 and 130 volts. The pressure was measured by a Cardew voltmeter, and by a Sir William Thomson electrostatic voltmeter. I calibrated the Cardew voltmeter by means of a Clark standard cell, and its indications agreed perfectly with Sir William Thomson's instrument. The currents between 7 and 26 amperes were measured by a Sir William Thomson ampere balance, and the current of 0·65 ampere was measured by a Sir William Thomson deci-ampere balance. With the larger currents the readings were taken every quarter of an hour, and with the smaller currents they were taken at longer intervals. In this case the current was taken through a single lamp from a secondary battery ordinarily supplying 40 lamps, and was therefore absolutely constant over a period of many hours, rendering it unnecessary to take frequent readings. The tests at high voltage (from 110 to 130 volts) were made whilst charging the secondary battery, and those at normal voltage (from 95 to 105 volts) were made whilst supplying the lamps from the battery when the current was direct, and whilst supplying the lamps from a transformer when the current was alternating. The conditions of the tests were therefore those which obtain in the actual use of meters.

The coefficient given by Dr. Aron for this meter is 1·07; that is to say, at about 100 volts pressure between the mains one division on the uppermost dial represents 107 watt hours. I first tested the meter in exactly the condition in which it came to me, and found that for currents varying between 25 and 15 amperes the coefficient given by the maker was nearly correct. For smaller currents the coefficient was, however, incorrect, and the error increased as the current was diminished. Thus, with current required for one single lamp, my test gave a coefficient of only 0·97. I found that this discrepancy was due to the fact that the meter had not been properly regulated before it was sent to me. In order that a clock-meter of this kind may register accurately it is necessary that the gravity pendulum should have exactly the same period as the electric pendulum when no current is passing. In this meter the gravity pendulum had a longer period, and consequently the meter registered, even when no current is passing. This defect can very easily be rectified, since the gravity pendulum is provided with a weight which can be screwed up or down as may be required in order to bring the two pendulums to absolute synchronism. I found it very easy to make this regulation, and my subsequent tests were made with the meter so regulated. I mention this matter to draw your attention to the necessity of regulating every meter after it is installed.

Test of Meter with Direct Currents.—The meter being intended for a 40-light installation, it seemed advisable to test it within the limits of current which would ordinarily obtain in such an installation. I made, therefore, prolonged tests with currents of 8 and 23 amperes, which corresponded to 12 and 35 lamps respectively. The coefficients I obtained were the following:—With 35 lamps, 1·30; with 12 lamps, 1·141. I also made a prolonged test with a single lamp, in order to determine the accuracy of the meter at the lowest current at which it can possibly be used in practice. This test is for all meters the most severe, since any error, however small absolutely, becomes relatively large if the current to be metered is very small. I found that, even at the lowest limit of current, the Aron Meter gave a remarkably accurate result, the coefficient being, with one lamp, 1·146. On the basis of these figures it is now possible to form an estimate of the accuracy of the meter when in practical use. Taking the mean between the coefficients for 12 and 35 lamps, I find 1·1355 as the coefficient to be used with this meter. The maximum error which would obtain if the meter were always worked at the lower, or always at the higher limit of current, would then be one-half per cent.; but as in practice the meter will generally be worked at intermediate currents the probable error will be less than one-half per cent. I need hardly say that this degree of accuracy is greater than that of any gas meter, and more than sufficient for all practical purposes.

Test of Meter with Alternating Currents.—As there must necessarily be some self-induction in the fine wire coil forming the bob of the electric pendulum, the shunt current must lag behind the main current, and the acceleration will be somewhat less than with a direct current representing the same energy. It will also be evident that the difference will be the greater the higher the frequency of the alternating current, so that the coefficient of the meter, as found by experiment with direct currents, will not be applicable if the meter is to be used with alternating currents, and a new coefficient must be experimentally determined for every

* Mr. C. V. Boys, F.R.S., in his Cantor Lectures on "Instruments for Measuring Radiant Heat" (April, 1889), has also shown that galvanometers with small coils may be made very sensitive (pp. 22, 23).

Digitized by Google

frequency. I have accordingly tested the meter at two frequencies, which may be considered limiting values for practical work, viz.: 105 cycles per second (or 12,600 reversals per minute). As regards current strength, I have in both cases made the tests within the same limits as those I adopted for the direct currents, and I give the results in the following table:—

Number of Lamps supplied.	Coefficient for a frequency of 105	70
35	1·95	1·170
12	1·220	1·194

Taking, as before, the averages between these figures, I find that the coefficient to be used with this meter is—

1·207 for a frequency of 105, and
1·182 for a frequency of 70.

In either case the maximum possible error is 1¼ per cent, whilst the probable average error will be considerably smaller than 1¼ per cent. This degree of accuracy, though not so great as that found with direct currents, is still quite sufficient for all practical purposes.

The energy absorbed in the meter varies with the current passing through it. At a pressure of 100 volts the energy absorbed is—

With 1 lamp ..... 3 watts.
With 12 lamps ..... 4 watts.
With 35 lamps ..... 9 watts.

My experiments lead me to conclude that the accuracy, long range, and economy of power shown by the Aron Meter make it a very satisfactory instrument, both for direct and alternating currents.

Yours faithfully, GISBERT KAPP.

THE METROPOLITAN BUILDING ACT.

We are indebted to Mr. Crompton for the following copy of Mr. Slater's letter on the subject of the Metropolitan Building Act, and its bearing upon the construction of central stations, which was referred to at the last meeting of the Electrical Trades Committee.

Copy.

January 21, 1890.

DEAR CROMPTON: In answer to your inquiry as to the points in connection with the Building Act which operate most oppressively with the new electric lighting central stations, I may mention:

1. Size. The limitation of a building strictly to 216,000 cubic feet may prove a most awkward restriction, and I understand that the London Electric Supply Corporation have a clause inserted in their Act to the effect that the limitation should not apply to them. What in my opinion should be done is that a clause should be inserted in the Building Act to the effect that if any one wishes to build a factory of a larger size than that stipulated, the County Council should have power to sanction it upon being satisfied with the method of construction, if it is in their power to sanction it at all.

2. It frequently happens, as was the case at Knightsbridge, that part only of a station is built at first, and a wall of a temporary character is required, but although this wall may adjoin no other property, it must be built in all respects, as to thickness, openings, &c., in accordance with the Act, as if it adjoined a thoroughfare.

3. A small workshed or office cannot now be erected on a site unless it is enclosed with brick walls (preventing very useful galvanised iron buildings) without the special sanction of the Council. I think the district Surveyor ought to have the power to sanction such a building, upon satisfying himself that it will not cause risk to other buildings.

4. Buildings of the warehouse class are compelled to have their roofs of a certain pitch which is very low, and thus it would be impossible to build a mansard roof containing living rooms or offices over an electric lighting station. This seems to me a perfectly useless and harrowing restriction, and I cannot imagine why it is insisted upon. My recent consideration of the Building Act and Amendment has forced me to the conclusion that a strong consolidating Act for the whole of London, controlling building operations, and preventing the disgraceful jerry building that goes on in all quarters of the metropolis is urgently needed, and if your Chamber of Commerce could urge this it would be doing a very good work. The present work barely touches the speculating builder, but harasses at all points the man who wants some new arrangements. [Signed] J. SLATER.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *January* 25, 1890.

The Establishment of Electric Light Associations.—The movement set on foot some months ago for the establishment of electric light associations in various States is already assuming encouraging proportions, and promises to have important results. Some seven or eight States have already fallen into line, and among them may be mentioned Massachusetts, Maine, Connecticut, New Hampshire, Rhode Island, Maryland, Michigan, and Illinois. This week New York participated in the movement, and steps for the formation of a New York association were taken at Albany. Before many months have gone by it is likely that most of the States of any size or population will have given in their adherence to the plan. In New York, more perhaps than anywhere else, this movement for the protection of established interests has been found necessary. As I wrote you in my last letter, it is already proposed to extend throughout the State the supervision now exercised by a Board in this city, so that all the electrical companies of the State will be subject to control and official direction, very much in the same way as the railroads are. It is evident that the operation of such a commission must be carefully watched, and, if necessary, met with opposition, or, when in the line of growth, its good work assisted to the fullest extent possible. By the time the annual meeting of the National Electric Light Association is held at Kansas City, the movement above indicated will have grown to such a size and taken such definite shape that I have no doubt that it will be found necessary and expedient to bring the national body into some kind of affiliation with these State organisations.

Agitation for the Repeal of the Copper Duty.—Another matter of general interest to electrical communities that is being agitated at the present time is the repeal of the duty on copper. A petition was presented last week to the Committee on Ways and Means of the National House of Representatives asking that action be taken for the abolition of the duty on copper ingot, plate, bars, rod, and wire. An address was made by Mr. George M. Phelps in presenting the petition, in which he stated that the electrical lighting industries interested represented a capital of no less than $275,000,000, and has already established some 238,000 arc lights and 2,700,000 incandescents. It was estimated that in the total cost of electric plant for light and power work, the outlay for copper was from one-quarter to one-third of the whole, and hence the copper duty was a serious tax upon the industry. At the same time the duty seemed to be wholly superfluous as a protection to American producers of that metal, for the United States not only exported the metal, but possesses the finest copper mines in the world. The result of the tariff, therefore, was simply to enable mining companies and dealers in copper to establish and maintain excessive prices through combination for that purpose. In view of these facts, therefore, and seeing that the duty on copper was at once useless for revenue and unnecessary for production, the Association, Mr. Phelps said, was of the opinion that the copper tariff should no longer remain in existence, it being the duty of the Government not to lend its assistance to any process by means of which combinations for maintaining the prices of the raw material artificially could be assisted to success. Of course, this line of argument is narrowed down strictly to copper, and, so far, has the support of almost everyone connected with electrical pursuits, it being impossible to blind oneself to the bad effects of the high price of copper on the development of electrical industries. It is evident, however, that such an argument has a somewhat wider scope and sweep, and could well be made to apply to other materials that are equally needed for the perfect industrial development of the resources of the country.

American Opinions on the Deptford Station.—There is quite a little interest, I may almost say anxiety, felt in this country amongst a great many electrical engineers as to the long delay in starting the huge Ferranti station at Deptford. A great many of us have been waiting from week to week for

Digitized by Google

its going into operation, and it is no exaggeration to say that its success would be the means of stimulating not a little work in this country along the same lines. But the continued delay has proved somewhat disheartening to the advocates of extreme high tension on the Ferranti plan, and at the present time not a few rumours and reports are current in this city as to the reasons why the station does not start up. Some of the reports go so far as to say that Mr. Ferranti is not only making material changes in his machine, but in his novel form of circuit, and also intends to operate for some time to come at a lower voltage than 10,000. Speaking of voltage reminds me that the fact has recently been elicited in this country that in Detroit some of the Brush circuits there have even been run as high as 9,000 volts by coupling up in tandem two or three of the regular series arc light circuits. I do not know whether this practice has to any extent been followed elsewhere, although it is understood that some few months ago, when so many of the circuits in New York were cut down, some of the remaining circuits were connected together and run at a very high figure in order to give the necessary service. There has been mention once or twice lately of large new arc light machines which would run up to 4,500 to 5,000 volts; and I have heard it said that one of these machines, as if by irony, is to be installed at Orange, where Mr. Edison lives. It is hoped that where these high voltages are adopted the line construction and insulation will be as good as they can be made; and after all, perhaps, when all the proper pains and precautions have been taken, there is no great difference between 2,000 and 5,000. But we shall probably wait to learn a little more from England about Mr. Ferranti's 10,000 volts of alternating current before we make any very serious efforts in that line ourselves. I need hardly say that in a country like this, where so much is put on a single throw of the dice, and where one of the predominant characteristics of business life is an absence of caution and an excess of daring, there has been no little admiration of Mr. Ferranti's pluck; but evidently this is one of the cases where a man must be judged by the results. On one point at least the opinion of American engineers has for some time been practically unanimous, and that is that Mr. Ferranti made a serious mistake in proposing to concentrate all his generating capacity for so many hundreds of thousands of lights in one station. We are likely to see in this country larger stations than any we have yet had; but in no cases in the large cities will there be an endeavour to put all the eggs in one basket. We shall see a continuance of the plan of dividing up the capacity in a number of stations, and then, as far as possible, connecting up into one whole the different networks of distribution proper to each station, thus reducing to a minimum the possibility of any cessation of supply in any one district.

Development of the Westinghouse Company.—It may be interesting to note that, owing to the recent great growth in its business, the Westinghouse Electric Company proposes to move its works out from Pittsburgh, and to establish large new factories a short distance from that city. It contemplates the development, in short, of a new industrial community, which will be devoted exclusively to electrical work, just as Pulman, for instance, is devoted to car building. As far as I am aware, this will be the first electrical enterprise that has thus given birth to and maintained a town by itself. At the present time the Westinghouse Electrical Works are said to employ 1,000 to 1,200 hands, and it is claimed that in a short time the electrical enterprises thus gathered together in their new home will employ no less than 4,000 to 5,000. There can be no question as to the enormous activity of the Company at the present time—an activity which seems likely to be maintained, and even increased, with the development of various new electrical inventions and enterprises. The Company is reported to be very busy just now getting ready for an extensive exploitation of its new alternating current arc light system, and it is also busy with its Tesla motor, of which an interesting and entirely successful application has just been made in mining work. It is understood that the Company will soon be ready to enter the electric railway field, and to make a bid for the business that there awaits attention.

Electric Traction at Boston.—The reports that I receive from Boston lead me to believe that, if all goes well, it will not be long before that city has an overhead electric railway in its narrower and more tortuous streets. It is said that the plans of the system are all made, though not yet open to general inspection, and that the structure and methods are a very great improvement over what has been previously done in that direction. The Thomson Houston Company, of course, has the work in hand, the enterprise being that of the West End Street Railway Company, which has already pushed the electric railway system so extensively and thoroughly in the more outlying parts of the city and in the suburbs.

BRUSSELS NOTES.

(FROM OUR OWN CORRESPONDENT.)

BRUSSELS, *February* 1, 1890.

The question of the electric lighting of Brussels, over which so much ill-feeling has been aroused owing to what is considered to be the undue preference shown to the Germans by the Conseil Communal, was somewhat hotly discussed at a recent meeting of the Société des Ingénieurs Industriels. M. Van Rysselberghe was the first speaker, and after holding forth against the German interlopers, proceeded to give some figures relating to his hydro-electric scheme, to which I have referred in previous letters. The Belgians are ready, said M. Van Rysselberghe, to supply current at 3·5 centimes per lamp-hour, and to hand over 10 per cent. of the gross receipts to the Caisse Communale. The Germans, on the other hand, propose to charge 5 centimes. In M. Van Rysselberghe's opinion, the electric current cannot be transmitted economically to great distances, since it is burdened with the law of Joule. According to the speaker, the cost of the hydro-electric scheme would be less than one-sixth of that of a three-wire installation. M. Van Rysselberghe was followed by M. Bède, who alluded somewhat warmly to the *chauvinist* attitude taken up by the Belgian electrical firms with regard to the tender of the German company. M. Bède asserted that the multiplicity of small dynamos involved by the hydro-electric scheme was a very wasteful feature, nor was he enamoured of the idea of running 35mm. pipes containing water at 50 atmospheres pressure under the streets of Brussels. With regard to the comparative cost of the two systems, M. Bède thought the figures cited by M. Van Rysselberghe would prove in practice to be very fallacious. Finally, M. Bède stated that the hydro-electric idea had been tried in Germany, and had proved a complete failure. Meanwhile the Commission d'Electricité has resolved to recommend the Conseil Communal to accept the proposals of the Société Internationale d'Électricité (Liége), of the Allgemeine Gesellschaft (Berlin), and of M. Van Rysselberghe, the district to be allotted to the German firm being the centre of the town. The feeling in favour of the electric light has, I may add, considerably cooled of late, owing to one or two ugly failures, due chiefly to bad workmanship, the result of the price-cutting mania which at present afflicts Belgian electrical contractors.

CORRESPONDENCE.

TRAINING FOR THE ELECTRICAL INDUSTRY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I was so pleased with your leading article on this subject in *The Electrician* of last week that I read it to my laboratory students. The sentiments expressed in your article are almost identical with those I have been instilling into the minds of the many young men who come here fancying that they will find some "short circuit" or "bye-path" into the profession of electrical engineers. Of the many sorts and conditions who attend our classes expecting to be "transformed" in a single term into electricians or electrical engineers, none tackle to their work more earnestly or pick up the elements of testing more rapidly than those who have served a complete apprenticeship to mechanical engineering. To the boy fresh from school who hopes to become an electrical engineer by simply attending a session of our lecture and laboratory courses, we point out the training which we ourselves went through, viz., two years at pattern-making, two at turning metals, two at finishing and erecting steam engines and boilers, some months at moulding, two years in the drawing office, and three sessions at the University Science Classes, before being fit to

Digitized by Google

act as an assistant in the manufacture and laying of submarine cables!

You say, "Nearly all large engineering firms derive a considerable income from premiums paid by the sons of wealthy parents. . . . Those boys who enter without premiums as bound apprentices have such long hours of labour, and so few chances of acquiring an all-round knowledge, that few of them can hope to become fully-trained . . . "

Such views do not agree with the state of matters on the Clyde, for here very few firms will take a premium, or even a bound apprentice. The lad, whoever he is, works for what he is worth, and he can have here in the evenings a complete training in mathematics, natural philosophy, engineering, drawing of all kinds, chemical and electrical engineering, lectures and laboratory work, as well as experiments with, and descriptions of, machines and steam engines. If the apprentice goes to his work by 6 a.m., and gets free therefrom by 5 p.m., what is to hinder him from attending such classes regularly twice a week from 7:30 to 9:30 p.m., and to study at home for two hours on at least two other evenings per week? If such a course should be too hard for him (we have over 1,000 students doing it in full at present), then he can attend our day classes and laboratories for the same subjects, and take things more leisurely. There is one thing certain: we cannot turn out from a technical college a full-blown electrical engineer, but we can and have often produced very competent electricians who were either content to remain electricians, or who went and picked up the necessary mechanical and commercial knowledge in a manufactory. Some of the largest and best firms have applied here direct for competent electricians—men capable of taking charge; and having got them, seem perfectly satisfied with their abilities and knowledge, whilst others applied for mere apprentices.—Yours, &c.

ANDREW JAMIESON, Prof. of Engineering.

The Glasgow and West of Scotland Technical College Electrical Engineering Laboratory,
Feb. 4th, 1890.

OVERHEAD WIRES AND THE ELECTRIC LIGHT.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I cannot understand the prejudice of the public to overhead wires, and in your article of last week's edition upon this subject you mentioned "that there are ways of doing overhead work, however, that would be inoffensive, inexpensive, and safe." I am firmly of the same opinion, and that if such an appliance as an indiarubber compensator, as I mentioned in my article to *The Electrician*, January 6, 1888, were used, there would be no danger from the breaking of overhead wires, and, save for a small area, the breaking up of roads and laying costly mains. Therefore, I think if these compensators were used they would, in the case of overhead electric light wires, meet with the requirements of the Board of Trade.—Yours, &c., R. S. BOZON.

12, Robert-street, Brighton, February 5, 1890.

DOUBLE BREAK SWITCHES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Noticing in your issue of last week that you describe and illustrate a double break switch by Messrs. Woodhouse and Rawson as *new*, I would draw your attention to those made by my firm and patented December, 1888. These switches were shown at the Building Trades Exhibition in August last, and again at Bingley Hall, Birmingham, and illustrated in the Exhibition Number of *Electrical Plant*. They have also been illustrated in one of my firm's switch catalogues during the whole of last year.

I have pleasure in sending you blocks of Simple Double Pole Switches, also one illustrating a six-way switch working on the same principle.—Yours &c., ARTHUR C. COCKBURN.

London, February 5, 1890.

[We hope shortly to publish a brief description of these switches.—ED. *E.*]

TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning.*]

"The Electrician" Electrical Trades' Directory and Handbook for 1890.

We have pleasure in announcing that the new edition of our Directory and Handbook is now ready, and orders already in hand will be executed to-morrow and Monday. The book consists of 850 pages, and has entailed this year an exceptionally heavy amount of work. We believe the book will be found very accurate, much care having been taken to make it so. There are several features of great present interest to the Electrical Trades in the Literary Section of the book, notably a Digest of the Law relating to Electric Lighting. Much attention has been devoted to compiling a reliable list of County Council, Borough Council, and other Local Authorities' officials throughout the United Kingdom; and every effort has been made to render the book useful. The Colonial and Foreign Division will be found extensive and reliable. Orders should be forwarded at once.

TENDERS INVITED.—The guardians of the Hackney Union invite tenders for supplying and fixing a dynamo, cables, wires, lamps, fittings, &c., for lighting the workhouse extension, infirmary, pavilion, board room, and office at Homerton, London, E. Firms tendering will obtain all particulars from Mr. Walter Barnett, surveyor, Winchester House, Old Broad-street, E.C. Tenders must be delivered to Mr. J. Owen Perry, clerk to the Union, by 1:45, p.m., on Wednesday next, the 12th inst.

——— The Town Council and Borough of Barnsley invite proposals for the supply of the electric light for public and private purposes. All information and forms can be obtained of Mr. J. Henry Taylor, C.E., Borough Surveyor, Barnsley, and proposals must be delivered to Mr. Henry Horsefield, Town Clerk, Church-street, Barnsley, by 10 a.m. on Friday, the 28th inst. Further particulars of the above will be found on page xv. of our advertisements.

LONDON COUNTY COUNCIL.—We learn that the Standing Committee of the London County Council are prepared to unanimously recommend Mr. Binney, of Bradford, for the office of chief engineer to the Council, rendered vacant by the resignation of Mr. Dunscombe through ill-health. It will be remembered that Mr. Dunscombe recently succeeded the late Mr. Gordon.

ELECTRIC MOTORS FOR WORKING TELEGRAPH INSTRUMENTS.—We learn that Messrs. Shippey Brothers (Limited) have recently supplied the Column Printing Company with one of their new type ⅛ horse-power standing motors, wound for 13½ volts. It is driven by a 9 volt C C battery with lifting arrangements, in order to regulate the speed of the motor. The cylinder is fitted with Prof. Wheeler's automatic regulator, which varies the speed according to the requirements of the work done. The motor is, we understand, giving every satisfaction.

MESSRS. ALLPRESS AND BELSHAW.—This firm have removed from 49, Victoria-street, and have taken more commodious premises at 55, Victoria-street, London, S.W.

DISSOLUTION OF PARTNERSHIP.—Messrs. Chappell and Co., of Heathfield, near Bovey Tracy, electric carbon manufacturers, have dissolved partnership.

NATIONAL TELEPHONE COMPANY'S SCOTTISH DIRECTORY.—We have received the new edition of this Directory, which bears evidence of considerable increase in the number of subscribers over that issued for 1889. It is very neatly got up, and contains the name of every exchange subscriber in Scotland and Cumberland.

PERSONAL.—The inspectors and over fifty workmen of the Liverpool Electric Supply Company dined together at the Falcon Day Hotel, Lord-street, on the 31st inst., and presented a marble timepiece to the retiring chief inspector, Mr. A. Lester Taylor, who has recently gone into business at 40, Burdett-street, St. Michael's, Liverpool.

THE AGRICULTURAL ENGINEERS' ASSOCIATION.—Mr. Cooper Corbidge, F.C.A., of the firm of Camm, Corbidge, and Co., has been appointed secretary of this association.

The Telephone in Russia.—The St. Petersburg correspondent of *The Times* reports that successful telephonic experiments have just been carried out between St. Petersburg and Moscow, a distance of nearly 500 miles, over the ordinary telegraph wires.

LEGAL INTELLIGENCE.

International Cable Company (Limited).

The petition presented by A. S. Bolton for the winding up of this company was again before Mr. Justice Stirling, in the Chancery Divison of the High Court of Justice, on Saturday last.

Mr. HASTINGS, Q.C. (with him Mr. Grosvenor Woods), asked that the petition might stand over, with liberty to cross-examine the deponents upon their affidavits. He said the company was formed to lay a cable under a Portuguese concession, and the petitioner alleged that the concession had been forfeited. This was denied on behalf of the company, and therefore he wished to cross-examine the persons who so stated.

Mr. BUCKLEY, Q.C. (with him Mr. J. Chester), on behalf of the company objected to any adjournment, alleging that the petition was a demurrable one. The petitioner, when sued for his calls, by way of retaliation presented the winding-up petition.

Mr. HASTINGS said the petitioner was a man of large means, and perfectly able to pay his calls.

His LORDSHIP said he would deal with the question of demurrer at once.

Mr. HASTINGS then read the petition, from which it appeared that the company was incorporated, with a capital of £1,000,000 in £10 shares, to lay cables between the Azores, West India, Canada, the United States, and Great Britain; that within the last few months the concession from the Portuguese Government had lapsed, and that no renewal could ever be obtained. It was further alleged that moneys had been improperly paid to the promoters, that the directors had gone to allotment without sufficient shares being subscribed for, that the company had not commenced business within a year of its incorporation, and that, in fact, the substratum of the company had entirely gone. The learned counsel said there was a distinct allegation that the object of the company was the connection of Portugal with the Azores and the continent of America, which could only be done under a concession from the Portuguese Government, and that this concession was gone, and, therefore, upon the authorities there was an entire loss of the substratum of the company, which justified the petitioner in asking the court for a winding-up order. In support of this proposition he cited the cases of the Haven Gold Mining Company and the German Date Coffee Company.

Mr. BUCKLEY said the allegation that the company had not sufficient capital was not enough to obtain a winding-up order. No doubt the petitioner was disappointed in not having received orders for copper wire which he would have set off against his calls, but that was no reason for winding up a company which was carrying on the business for which it was incorporated. The petitioner was not supported by a single shareholder. He suggested that this was not a *bona fide* petition, but was presented with an ulterior purpose.

His LORDSHIP having expressed an opinion that the petition was not demurrable,

Mr. BUCKLEY said he would not press his objection further.

Mr. WARRINGTON said he appeared for shareholders representing £34,000, and he supported the petition.

Counsel for shareholders holding 1,100 shares and creditors to the amount of £700 said he was instructed to oppose the petition.

His LORDSHIP ordered the petition to stand over until after the cross examination was completed.

Hinds v. Smith—Christopher v. Same.

These were appeals before Mr. Justice Denman and Mr. Justice Wills, against orders by Mr. Baron Pollock dismissing or staying various actions against the Right Hon. W. H. Smith, Sir John Hawkshaw, Sir Joseph Whitworth, Lord Alfred Paget, and others, Directors of the Old Electric and International Telegraph Company, incorporated by special Act in 1846. The statement of claim in each case was alleged to be the same, with the exception of the names. The statement was a long and complicated document, from which it was difficult to gather any cause of action. The plaintiff Hinds, who appeared in person, was said in the statement of claim to be the surviving partner of the late Thomas Allan, of Edinburgh, electrician. The claim stated that T. Allan came to London in 1849 and became the pioneer of electric telegraphy and light, submarine ropes, &c., and spent much money in this pursuit; that in 1851 a local Act, 13 and 14 Vict., cap. 137, granted to him the right to work a patent in the name of the United Telegraph Company. The claim stated that the profits of the Electric and International Company through working a concession granted to Allan in 1852, and up to January, 1870, the date of the transfer of the telegraphic undertakings to the State, amounted to about £1,000,000.

The Court read the statement of claim through, and came to the conclusion that it was frivolous and vexatious, and accordingly dismissed the appeals.

Mr. HINDS claimed a right to read the statement of claim through, and referred to section 24 of the Judicature Act, 1873. He became abusive to the Court, and was repeatedly ordered to be quiet. This order he disobeyed, and the usher was directed to remove him.

Mr. JUSTICE DENMAN ultimately committed Mr. Hinds to prison for seven days for contempt of Court.

The Court dismissed all the appeals, holding that when the action was gone the right of amendment was gone too.

COMPANIES' MEETINGS & REPORTS.

Anglo-American Telegraph Company (Limited).

The ordinary general half-yearly meeting of the proprietors of this Company was held at Winchester House, Old Broad-street, on the 31st ult., under the presidency of the Right Hon. Viscount Monck.

The SECRETARY (Mr. T. H. Wells) read the notice calling the meeting and the minutes of the last meeting, which were confirmed by the present meeting and signed as correct by the Chairman.

The CHAIRMAN: Gentleman, I presume you will take the report as read, and in moving its adoption I am happy to be able to announce a small addition to the dividend which we have been lately able to declare to you. The addition undoubtedly is small, but I think, in connection with the explanation contained in the report, it is not discouraging, and it contains the element of hope for the future. Gentlemen, you are aware that we are carrying on our traffic under two distinct arrangements—with the Direct United States Cable Company and the Western Union Company of New York. We have what is called a joint-purse arrangement—that is to say, we each pay our receipts into a common fund, and receive from it proportions of the aggregate. On the other hand, the parties to this joint purse arrangement and the Commercial Cable Company of New York have an agreement by which the tariff is fixed at a certain rate, and they each take as much as they can get at that rate. I believe that that arrangement has been fairly and honourably carried out on both sides; but it must be apparent to you that it introduces the element of competition, and that any circumstance which might arise to interfere with the carrying power of either of the parties to that transaction would affect their income. This is precisely what has happened to us during the past half-year. During that time one of our own cables—the old Brest cable of 1869—was twice out of working order. The cable of the Direct United States Company was also for a while inoperative. The two cables of the Western Union Company were also disabled, while during the whole of the time the cables of the Commercial Company, who are our competitors, were working uninterruptedly and with good effect. Gentlemen, with reference to this matter, I have only to reiterate and in every way to emphasise the observation made by my honourable friend, the Chairman of the Direct Cable Company, that it is the first duty of the Boards of the associated Companies to keep their cables constantly in repair, and whenever a mishap occurs to take care that the repair shall be effected with the greatest possible expedition. This is, of course, only the fortune of war. We have no right to complain of it, and I only mention it to you as the reason why we are not able to distribute a larger dividend than we propose on this occasion. Our cables are now in good working order. I hope they may continue so, and that the improvement in trade which has taken place all over the world may affect our traffic, and enable us to do better for you in the future. With respect to the expenses of the past half-year, on the face of them they look larger than those of the previous half-year; but if you come to analyse them, you will find that the increase consists altogether of extraordinary expenditure—restoration of buildings and so on—which is not likely to recur for a long time, and which cannot be treated as normal expenditure. During the period I speak of there has been spent on these objects at St. Pierre £1,000, at Valencia £1,000, at Heart's Content £400, and at Duxbury £200, making in all £2,600, which very largely exceeds the excess of expenditure shown in the accounts. Within the last year we have executed two works, one of which was alluded to by my noble friend at the last meeting—the diversion of the St. Pierre-Duxbury cable into deeper water. It has been for many years a source of vexation and expense to us by its liability to injury from the shallowness of the water in which it was laid. I trust now that it will give us much less trouble. The other operation which has been performed, and which has been referred to in the report, is that by an arrangement with the Western Union Company we have obtained the use of two wires into New York City, where we have established an office of our own, which will put us in direct communication with our customers at New York, whilst the extension of the Western Union Company's cables into New York will obviate the inconvenience—which from my residence in New York I can speak of with personal knowledge—of the interruptions of the land lines in the winter and spring by snow and storm. Gentlemen, we have often had discussions in this room with reference to the renewal fund. I do not want to raise any question about it on this occasion, but I think it will be satisfactory to you to know that the fund, which now stands in our books at £923,344, has been so well invested that it is worth, at the prices of the present day, about £60,000 more, and will give you in case you require to use it, with the spare cable in reserve, a full one million sterling for any purpose for which you may wish to apply it. I think this is not an unsatisfactory state of things so far as that is concerned. Since our last meeting this Company has sustained a great loss in the death of one of its most prominent members, Sir Daniel Gooch, who was an original member of the Board of this Company, and contributed by his personal exertions almost as much as any other man to the establishment and development of ocean telegraphy. In his profession he was a most eminent man, and his modesty was equal to his merits. It would have been impossible to have been connected, as I was for nearly twenty years, with such a man without having been impressed by his great intellectual abilities, and even more so by the high moral attributes which characterised him. Gentlemen, I think I express your feelings in thus giving utterance to our appreciation of the work of Sir Daniel Gooch, and our regret at his loss. We have chosen into his place Mr. Charles Burt, who is known to most

Digitized by Google

of you, and who, from his long experience of the business of the company and his great capacity, is, in my opinion, a worthy successor to Sir Daniel Gooch. With these observations I beg leave to move:

"*That the report of the directors and accompanying statement of accounts to December 31, 1889, submitted to this meeting be and the same are hereby received and adopted, and that the following dividends, less income-tax, as recommended by the Board, be now declared and paid—that is to say, a final dividend of 15s. per cent. on the ordinary consolidated stock for the year ended December, 1889, making, with £2 per cent. interim dividend already declared and paid by the Board by way of dividend on account, a total dividend for the said year of £2. 15s. per cent: upon the said stock, and a final dividend of £1. 10s. per cent. upon the Preferred ordinary stock for the year ended December 31, 1889, making, with 4 per cent. interim dividends already declared and paid by the Board by way of dividends on account, a total dividend for the said year of £5. 10s. per cent. on the said stock.*"

The MARQUIS OF TWEEDDALE seconded the motion.

Mr. JACKSON said he desired to ask two questions before the motion was put. His friend Mr. Smith, who for so many years had taken an active part at the meetings, had been compelled by a severe domestic calamity to be absent on that occasion, and had requested him to express on his behalf his general satisfaction with the report. Mr. Smith had desired him to ask a question with reference to the litigation with the French Cable Company. The Chairman had not mentioned it, but it was a deeply-interesting subject to the shareholders. If it had been a personal matter in which the estate of the Board had been concerned he did not think that so much delay as two years would have occurred, and that there would have been such a result as they now saw brought about. They had been hung up for two years, with the prospect of a further delay, and no satisfactory conclusion had been arrived at. He thought they might under the circumstances venture to ask the Board to use their best endeavours, and by using a little elbow grease, to use a vulgar phrase, endeavour to get a settlement arrived at by urging on the consideration of the French Government what he considered a scandal and a disgrace. The Company had a very strong case, and the French Company were endeavouring to benefit by their own *lâches*. The French Company, under the auspices of M. Pouyer-Quertier, had entered into a contract with the Anglo Company, and under the present administration that contract had been absolutely violated, and the shareholders had no evidence at present that any progress was being made in the matter. He hoped the Chairman would be able to assure them that everything had been done, and would be done to arrive at a settlement. They had heard that the French Company had taken out of the "pool" receipts somewhat exceeding £200,000 beyond what they had contributed to it. That was a very strong fact. The Anglo Company went to the Tribunal of Commerce, which one would have thought would be the special tribunal to judge such a case. There the verdict was given in the Anglo Company's favour, but it was appealed against by the Company which had captured the French cable, the decision there being confirmed. Then recourse was had to the Prefecteure de Seine, which was a political association, which had said that the contract was *ultra vires*. The consequence was that the matter was hung up all this period, and he thought that the shareholders had some right to urge on the Directors to use every exertion to bring the matter to an issue. This point, however, he raised mainly on behalf of Mr. Smith. His own question referred to a point upon which the Chairman had touched. Sir John Pender, at the meeting of the Direct United States Company, remarked, as the noble Chairman had just now mentioned, that it was the duty of the associated Companies whenever a cable was down to lose no time in repairing it, because the power of the Companies associated was then enlarged, enabling them to produce better results for the shareholders. There was another point which the Chairman had not referred to, which Sir John Pender had dealt with, and which he (the speaker) thought was a burning question with them. At the end of his speech Sir John Pender said that something must be done to increase the revenue of the Company, and he (Mr. Jackson) thought that the shareholders might call upon the Directors of the Anglo Company to associate themselves with Sir John in some way to produce a result which would be less inadequate for a trading company than they at present obtained. The starvation dividend of the funds was not one which a trading company ought to be satisfied with. The record of the Anglo Company was not a brilliant one. After 24 years' experience, with the advantage of great intellect on the Board, and men of unimpeachable position and integrity to conduct their affairs, they were only able on the face of it to pay a dividend of 2¾ per cent. In fact, it was only 2¾ per cent., for the shareholders would have observed that part of the expenses had been paid out of the interest which had been earned by the renewal fund. The total cost of the repairs for the half-year had been £37,000 odd, which was more than ½ per cent. dividend. Part of this had been paid out of the shareholders' savings—out of the interest of their accumulated fund which the Directors had so satisfactorily built up, with the assistance and patience of the shareholders. But he (Mr. Jackson) maintained that 2¾ per cent. was not a brilliant result, and one which they could not be satisfied with, nor could they congratulate their excellent Board upon it. Therefore, he desired to impress upon them the concluding observation of Sir John Pender at the meeting of the Direct Company, that something must be done to increase the revenue. When he (Mr. Jackson) joined the Company at its inception, the first tariff was a £2) message, and the next a £10 message. Afterwards the word system was adopted, and telegraphists had the opportunity of condensing their messages and reducing the expenses. But in the case of the Anglo Company the tariff had been reduced in the 24 years from the original amount to 5 per cent. He maintained that there was no record in this city of such a reduction. The Company, however, did not stop there, for owing to the coding system, which had become a high art, 20 words were enabled to be sent in one word, and the codists got the full benefit. He did not think that that was a fair condition of things for the shareholders. He, not being a merchant, had had occasion to send a message by the 3s. rate, and it cost him 14s. for the address. This was a question which the Board should direct their attention to, with a view of seeing if something could not be done to remunerate the shareholders for their long-tried patience. He had been glad to hear the Chairman say that they might look for a small and gradual improvement in the Company's affairs.

Mr. WOOD (Chislehurst) called attention to the following passage in the second paragraph of the report:—"For some weeks during the half-year under review, the whole of the traffic was thrown on to the cables of this Company, and, in consequence, its volume was sensibly diminished." He said he understood that the carrying capacity of their cables was far in excess of the business they had to do, and, therefore, the passage he had read rather astonished him. Mr. Jackson had referred to the dividends which they had paid for a good many years as not being very brilliant. That was so, but he (the speaker) was very thankful that they had not been worse. They might congratulate the Directors on one thing which was very brilliant in his opinion: that the Company had a reserve fund, with spare cable, amounting to the value of a million sterling, and he thought they might congratulate the Board on their foresight and prudence in having accumulated this fund. He regarded it as the backbone of the Company, and it made the concern a very much safer investment than many other companies that might be mentioned.

Mr. HUMPHREYS inquired the total cost of the repairs in the past half-year. In the revenue account the repairs were put down at £17,801, and he thought the whole of the repairs ought to be put to revenue account.

The MANAGING DIRECTOR (Mr. Weaver): You would not put it into revenue account if it were not chargeable to revenue?

Mr. HUMPHREYS asked what the total cost of the repairs for the half-year had been?

The SECRETARY: £17,801, *plus* the amount debited to the renewal fund.

Mr. HUMPHREYS said that that was just what his question referred to, and he strongly objected to what had been done. The amount of the repairs seemed very small, judging from the revenue account. The total expenses of the half-year, instead of being shown as £58,000, ought to appear as about £77,000. He thought that if these facts were always shown they would not be so continually stirred up by the threat of new cables being laid. The amount of the expenses stated in the report of £58,000 was misleading to the public, for the real fact was that the amount was nearly £80,000. He could not see anything to congratulate the Directors upon in the report. If the Directors were to have two Committees, one to attend to the electrical part of the business, and the other to attend to the financial part, he thought that the £2,600,000 Deferred Stock would soon come in for a better dividend. The Direct United States Company paid 3½ per cent. dividend and put by another 2½ per cent. to the reserve, and the Board of that Company were to be congratulated and thanked for the successful way in which they conducted their business. The Anglo Company, however, could not even pay a 3 per cent. dividend, but only 2¾ per cent., and that with difficulty, and they would not have been able to make this distribution if the renewal fund had not been charged with part of the cost of repairs. They ought not to divide their expenses with a fund which probably the general public never thought of looking at—the renewal fund.

Mr. JOHN NEWTON said that in the past the shareholders had strongly dissented from such large sums being put to the reserve or renewal fund, and if at the present time the revenue from the investments paid for part of the expense of the repairs he thought they ought to do so. In any case, however, the point raised was a matter of book-keeping, and he did not think it was for the shareholders to interfere with the judgment of the Directors as to how the books were kept. As long as the broad result was as it now stood the shareholders ought to be satisfied. He desired to express his satisfaction at the remarks which had fallen from the Chairman relative to the immense services which had been rendered to submarine telegraphy by the late Sir Daniel Gooch. Not only did the deceased gentleman advance the submarine telegraph system by the labours which he bestowed upon it, but by the money which he had put into the enterprise. No doubt he had received an abundant reward, but not half the amount that he ought to have received, and which the shareholders ought to receive for the grand work in which they had taken part. Magnificent divivends were paid by gas and water companies, who had not rendered half the services to civilisation which their Company had done, and they could not but feel dissatisfied with the amount distributed among them. He desired to express his satisfaction at the selection which the Directors had made of a gentleman from the City to fill the seat at the Board rendered vacant by the death of Sir Daniel Gooch. He preferred to see City men on the Board to gentlemen who came from the West End.

The MARQUIS OF TWEEDDALE: Our noble Chairman has asked me, as his voice is not as strong as it has been, to reply to the questions which the honourable proprietors have put to him. With reference to Mr. Jackson's question regarding the case in the French Courts, I can assure him and the whole of the shareholders present that everything has been done that could be done to bring it to a settlement. The intelligence of our lawyers, and of our able manager, has been directed to expedite the settlement of that case. I need not, however, point out to you that we cannot bring any influence to bear on the French courts; but we have reason to believe that that case may be settled before we meet you again in six months' time. With respect to Mr. Wood's question as to the last part of the second paragraph of the report, I think it is sufficient to point out to him that it is inevitable that a Company which loses three of its cables must be crippled with respect to the traffic which it may expect. The traffic, as you are all aware, between this country and America is crowded into a very few hours, and, of course, the more cables we have at our command the more expeditiously is the business transacted. With

Digitized by Google

respect to something being done to increase the income, that is, I need hardly say, the chief, if not the only, occupation which the Directors have to turn their attention to. Sir John Pender said that the time has come for doing it. I think the time came a good while ago for doing it if it were possible. But you must remember that the tariff cannot be fixed by ourselves. We have not only partners in this business—important and influential ones—but we have also got opponents, and until we all agree, and become a happy family with respect to this question of the tariff, it is impossible to make any alteration, even if an alteration were desirable. But I think the impression on our minds, and on the minds of our friends, is that it would not be desirable to make any alteration in the existing tariff. The tariff seems to meet exactly the kind of traffic which we have to convey. If we were to increase the tariff, there is every reason to suppose that we should bring in further competition. I think this is a general answer to a great deal that has been said to-day by Mr. Jackson. You must remember that the Atlantic Ocean is open to any number of persons who choose to spend their money or lose it in laying a cable. That is the difficulty which we and other Companies have to contend with respecting the income we should like to enjoy. With regard to the total cost of repairs, the total cost of renewals and repairs is composed of two items. Something like £17,000—nearly £18,000—includes the repairs of the Brest-St. Pierre cable, and the repairs and diversion of the St. Pierre-Duxbury cable. This amount was charged to renewal fund, and £17,800 was charged to revenue account for the expenses of the ship "Minia," the value of the cable expended and the charter of the "Britannia." These two amounts together come to about £36,000.

A SHAREHOLDER asked what sum was in dispute in connection with the litigation with the French Company.

Mr. CHARLES BURT: An unknown quantity—an enormous sum if we can get it all.

The SHAREHOLDER: It is not in the accounts?

Mr. BURT: Oh, no.

The CHAIRMAN then put the resolution in the usual way, and it was carried unanimously.

On the motion of the MARQUIS OF TWEEDDALE, seconded by Sir JAMES ANDERSON, Viscount Monck was re-elected a Director, as was also Mr. Samuel Barber, on the motion of the MARQUIS OF TWEEDDALE, seconded by Mr. FRANCIS A. BEVAN.

Mr. Joshua Dean was re-elected an auditor for the current year, and to fill the vacancy in the auditorship caused by the retirement, on account of failing health, of Mr. Francis Glass, Mr. John Gane was elected.

Mr. JACKSON then proposed a vote of thanks to the Chairman and Directors, and expressed the gratification which he was sure all the shareholders had at seeing Viscount Monck presiding over them again. His lordship's presence was a guarantee and an assurance to the shareholders that whatever could be done by goodwill would be done.

The motion was seconded and carried unanimously.

The CHAIRMAN briefly returned thanks, and the proceedings terminated.

The Cuba Submarine Telegraph Company (Limited).

The 37th ordinary general meeting of this Company was held at the Company's offices, 58, Old Broad-street, on Wednesday last, under the presidency of Mr. Thomas Greenwood.

The SECRETARY (Mr. James Scott) having read the notice convening the meeting, the report of the Directors (which we give below) and statement of accounts were taken as read.

The CHAIRMAN: Gentlemen, it is usual on occasions like this to direct your attention to the prominent features in the report in the order in which they are therein given; but I must ask you to-day to allow me to refer first of all to paragraph 9, because it relates to a personal matter. Mr. Low, who has been occupying the chair since the lamented death of Mr. de Mancha, felt it necessary to resign the duties which he had so honourably performed. I need scarcely say that the Board did their very best to induce him to withdraw his resignation, but when he gave the reasons he had for doing so, we felt it was necessary to relieve him at once of his duties, and that has been done. The Board have been good enough to request me to take the chair, and I trust, as Mr. Low has consented to remain on the Board, that he will give us the benefit of his very long experience and knowledge, for he has been a Director of the Company from the beginning, and that our affairs in the future will continue to be conducted satisfactorily to you, as I am sure they have been in the past. Turning to the accounts and the general business of theday, if you have made a comparison between these accounts and those of the corresponding period of the previous year, you will have noticed a number of small items not worth consideration to-day. There are two, however, of importance, upon which I wish to say a word or two. You will find that the expenses are about £1,500 more than they were twelve months ago, and that the receipts are about £1,500 less than they were at the same period. These two sums together make a difference in our available balance of about £3,000, and account for the fact that we have carried to the reserve fund this year only £1,000, as against £4,000 in the corresponding period last year. Adverting now to the item of expenses, you will perceive that the whole of this addition has been caused by the cost of the repair of the Batabano-Cienfuegos cable, and the amount paid to the Government for the use of their wire during the short time the cable was broken. Fortunately for us, twelve months ago we had no such repairs, but one does not expect to carry on a business of this kind without having at some time or other to encounter expenses in the repair of cables, and although it appears that there is a difference of £1,500, compared with the previous year, this arises solely from the fact that there were no expenses of this kind in that year. The average expenses for the last seven years for the repair of cables have been £2,338 per annum, and we have been obliged this half-year to charge to revenue about £1,500, which you will see is a little more than the general average. But if I were to leave my quotation of figures there it might mislead you, because the revenue of the Company bears a considerably larger sum than that for renewals and repairs; in fact, for the replacement of one of the cables—I refer to the 1881 cable—we charge against revenue £3,750 per annum, and that has been going on for nine years, and there are three years yet to come in which a similar amount will be charged to that account. But when that is done we shall have got our cable paid for altogether out of revenue, and no further expenses will appear under that head except repairs in the usual way. During the twelve years the contractor has to repair that cable, but when his last instalment has been paid we shall ourselves have to pay for any repairs that may have to be made. Adverting to the other side of the accounts now, that is to the diminution in the receipts by £1,500, I wish to observe that, although it may appear paradoxical to say so, it is nevertheless a satisfactory feature. We have reduced our tariff upon by far the larger portion of our business by some 25 per cent. The through rate used to be 67 cents per word: it is now 50 cents, and the Board congratulate themselves and you upon being able to make so large a reduction in our rates with so small a diminution in the average receipts. I am pleased to mention also that last month our returns were £3,150, as against £3,220 in the same month last year, or a diminution of only £70 comparing one month with the other; and we do hope that the increase of traffic which must necessarily come by the diminution of our charges will continue, and that we shall have as large an income at the reduced as we had at the higher rate of charge per word. I think that this must be satisfactory to the shareholders and everybody concerned, because it is manifest that no company can hold a monopoly such as we do without taking into consideration the needs of the public who use our lines; and our position will be firmer, and we shall be less likely to be opposed at the lower than at the higher rate of tariff. That brings me to make a remark or two upon the circumstances in which we are placed in relation to the French Cable Company. You will find the subject referred to in paragraph 6 of the report. The island of Cuba, as you know, is about six times as long as it is broad, extending practically from east to west, the long sides therefore being north and south. Our lines begin at Havana, on the north side, where they join the cables of the International Ocean Telegraph Company, whose lines connect Havana with the North American continent, so that messages to and from the West Indies must necessarily pass through that company's line and the Atlantic cables to Europe. From Havana our line runs overland to Batabano, on the south side of the island, whence our cables run along the south coast, touching at Cienfuegos, to Santiago, our terminus at the east end of the island. There we join the West India and Panama Company's system, which goes on to Jamaica, thence passing, but not touching Hayti, to the other islands included in that Companys' system. We have agreements with the West India and Panama Company, and also with the International Ocean Telegraph Company, by which we control the traffic through all these lines. But a French company was started some little time ago. It has laid cables from Venezuela, touching an island *en route* to San Domingo, and thence by a land line to the sea at the north side, and cable to Mole St. Nicholas, Hayti, not far from Santiago, where our lines commence. They had previously obtained permission to lay a line to Cuba, touching an insignificant place, and then continuing their cable from there to Santiago, so that messages to and from Venezuela and Europe pass *viâ* Santiago through our lines to their destination. All this is very satisfactory so far as it has gone, and our revenue has been considerably increased by the traffic which the French company bring to us, and we hoped that, by reducing our rate, we should have secured their traffic permanently. But that company has made application to the Government of Spain for permission to lay a line of their own from Havana, our western terminus, along the north coast to a point near Santiago, with which it now has telegraphic communication, so that, if that line were made, there would be direct competition between it and our own lines, for it is manifest that it makes no difference to anybody sending a telegram whether it goes by the north or the south side to the same place. Under the circumstances the Board felt it necessary not only to protest against this, but to use their best endeavours to get the Spanish Government to refuse the application. But having failed in that, they have initiated proceedings in Madrid with the view of annulling this Royal Order which, I understand, usually precedes the granting of any concession, and I hope we may succeed in doing this. But even supposing we do not, there are several things to be considered before we arrive at the conclusion that our traffic is likely to be interfered with. That company will have to get their capital for carrying out the concession, and when they have got the capital they will find that the cost of the line will make a great dip into a quarter of a million sterling. My own opinion is, that at the charge we make to them it would be much more profitable for them to send their messages by our cables than to lay one of their own, unless they have some ulterior object of which we have not been informed and can only surmise. Gentlemen, I think I have laid the facts of the case before you, and if there be any other information which the shareholders wish to have, I should be happy to give it, for both you and the Directors are in the same boat, and any knowledge which we possess, and which we can fairly give you without interfering with the business of the Company, we shall be most happy to supply. With these remarks I beg to move—

"*That the report and accounts for the half-year ended December 31st last now submitted, be received and adopted.*"

Digitized by Google

Mr. LOW seconded the resolution, which was unanimously adopted without discussion.

The CHAIRMAN then moved—

"That the following dividends for the half-year be now declared upon the shares of the Company, viz., at the rate of 10 per cent. per annum, subject to income-tax on the Preference shares, and 9 per cent. per annum, free of income-tax, on the ordinary shares, payable on and after to-morrow."

Mr. LOW seconded the motion, which was carried *nem. con.*

Mr. KEENLYSIDE proposed a vote of thanks to the Chairman, the Directors, Secretary, and staff for their successful conduct of the Company's business.

Mr. JOHN PITCHFORD seconded the motion, which was carried unanimously.

The CHAIRMAN: On behalf of the Board I have to thank you very much for your appreciation of their services. I can assure you they have done their best, and are satisfied to think that they have pleased the shareholders, which they hope to continue to do. As the Secretary's name has been mentioned, I should like to say that, though my period of this office has been short, I have been acquainted with Mr. Scott for many years, and I do not think it would be possible for us to have a more efficient Secretary, or one who could take a greater interest in the welfare of the Company.

The proceedings then terminated.

The following is the report of the Directors for the half-year ended December 31st last, referred to above.

1. The balance sheet and accounts are for the half-year ended December 31st last.

2. From these it will be seen that the gross receipts (including the balance brought from last account) amount to £19,705 18s. 2d., and the gross expenditure (including the half of the annual payment on account of the 1881 cable, and the expenses in connection with cable repairs) to £8,101 6s. 8d., leaving a sum of £11,604 11s. 6d. to the credit of revenue account.

3. Of this the sum of £1,000 has been added to the reserve fund, increasing that fund to £91,000.

4. The dividend on the preference shares will absorb £3,000, and leave £7,604 11s. 6d., out of which the Directors recommend the payment of a dividend on the ordinary shares at the rate of 9 per cent. per annum, free of income-tax, the balance, £404 11s. 6d., being carried forward to the current half-year's account.

5. The gradual and continuous increase in the income of the Company, together with the accession of business on the opening by a French Company of telegraphic communication from this Company's terminus in Santiago to Venezuela, warranted the expectation that a large reduction might be made in its through tariff without materially affecting the shareholders' dividend, and with a view to secure by its lines the permanent carriage of the French Company's through traffic to and from America and Europe, and also to increase the traffic to and from the West Indian Company's system, the rate for all through messages was reduced about 25 per cent. from July 1st last. It is very satisfactory to note that the aggregate receipts have suffered comparatively little by the change.

6. But the Directors regret to have to report that although the through rate has been thus reduced and all other proper facilities given to the French Company, that Company has applied to the Spanish Government for permission to have a line by land, or a cable by sea, almost parallel with the lines owned by this Company. Protests have been lodged by the Board with the Spanish authorities, but apparently without avail, for a Royal Order has been issued refusing the land line, but conditionally granting a cable from a place adjacent to this Company's eastern terminus at Santiago (with which town the French Company already has telegraphic communication), along the north coast to Havanah, this Company's western terminus, so that the proposed line, if allowed, will take from this Company the whole of the traffic under the control of the French Company, but now carried by this Company, and may be in competition, by the north coast, with this Company's lines on the south coast. The Board has therefore felt it to be imperative to commence proceedings in the proper Court in Madrid to protect this Company's concession and interests.

7. The duplication of the line between Batabano and Cienfuegos has been postponed until the next favourable season. The tenders invited by the Board were not completed, but were under the consideration of the cable manufacturers when the strike difficulties commenced. The tenders were very much higher than the Board expected them to be, and as the existing cable was working satisfactorily, the delay of a few months was deemed to be desirable. That cable has lately been broken by a ship's anchor, but has been speedily repaired, and is now at work as usual.

8. The Cienfuegos-Santiago 1875 cable, being faulty at both ends, will be repaired as soon as possible. The traffic is carried by the 1881 cable.

9. In accordance with Mr. Low's request he has been relieved of his duties as chairman, which have been undertaken by Mr. Greenwood, but the Directors are pleased to add that Mr. Low retains his seat on the Board.

City of London and Southwark Subway Company.

The following is the report of the Directors, to be presented to the shareholders at the eleventh half-yearly ordinary meeting of the Company, to be held at Winchester House, Old Broad-street, E.C., on Tuesday, the 18th inst., at 12 o'clock:—

During the past half-year the works of the Subway have made considerable progress and are now approaching completion.

The work of driving through the wet bed of gravel at Stockwell has been steadily proceeded with, and one of the tunnels is now completed throughout, and the other tunnel is being rapidly advanced. The underground stations are all nearly finished, and the station buildings on the surface at Great Dover-street are roofed in, the alterations to the building at King William-street have been completed, and the Company's offices are now established there. The hydraulic lifts are being erected at King William-street and Great Dover-street Stations, and the rails have been laid in both tunnels from the City to the "Elephant and Castle," and also for a considerable distance on the Stockwell extension. At the depôt at Stockwell the boiler-house has been completed and six boilers fixed. The engine-house is nearly ready for the reception of the engines and dynamos, and the carriage sheds are being erected. The inclined road leading from the depôt to the tunnels is nearly finished. Messrs. Mather and Platt have had an electric locomotive and carriages running experimentally for some time between the King William-street and Great Dover-street Stations.

As the present authorised lines stop at Stockwell, about a mile short of the great centre of traffic meeting near the "Plough" at Clapham, your Directors have deemed it advisable to deposit a Bill in Parliament asking for power to extend the line to that point, the works for which can be carried out at a lower comparative cost than the existing works, and the approval of the proprietors will be asked at a special meeting called for that purpose. They propose also to alter the name of the Company to that of the City and South of London Railway Company, as being more in harmony with the present nature and object of the undertaking.

Powers are being sought in the ensuing session of Parliament by an independent company for the construction of an underground railway on the same principles as the City of London and Southwark Subway, from Bayswater along Oxford-street and Cheapside to the City, with a junction with our line at Arthur-street West, just before it enters the King William-street Station. The junction as at present proposed would not be satisfactory to this Company, but it is possible that arrangements may be made to

effect a junction between the two lines beneficial to both companies. It has also been deemed expedient to include powers in the Company's Bill for the acquisition of the necessary land for the construction of a station near the London Bridge termini of the London and Brighton and South-Eastern Railways.

The Directors who retire by rotation are Messrs. C. S. Grenfell and Alexander Hubbard, who are eligible for re-election.

The Auditors likewise offer themselves for re-election.

The India-Rubber, Gutta-Percha, and Telegraph Works Company (Limited).

The following is the Directors' report for the year ending Dec. 31, 1889, to be presented at the twenty-sixth ordinary general meeting of the shareholders, to be held at the Cannon-street Hotel, on Friday, the 14th instant, at half-past one o'clock:—

The accounts show the net profit for the past year to be £57,748. 9s. 1d. Adding £25,087. 17s. 7d. brought forward, and deducting £20,800 interim dividend paid in July, there remains a disposable balance of £62,036 6s. 8d. The Directors recommend the distribution of a dividend of 10s. per share, free of income tax, amounting to £20,800, making, with the interim dividend, a total payment for the year of 10 per cent., and leaving £41,236. 6s. 8d. to be carried forward. The Company's general business has been well maintained; and the laying of the 800 miles of cable mentioned in the last report was successfully completed. At the instigation of unprincipled agitators, almost all the Company's workpeople went out on strike in the middle of September, and remained out from ten to twelve weeks. The result to them was the loss of about £20,000 which they would have received in wages. The loss to the Company was but small, as other means were available for the execution of orders. For the greater convenience of the Company's business, freehold premises have been purchased at Liverpool adjoining those hitherto occupied, the lease of which runs out in the present year; and in consideration of an extended lease at a reduced rent, the premises in Cannon-street have been rearranged and greatly improved, and fitted with electric light. The Company's works and machinery are in efficient working order.

Mr. Silver and the Hon. Henry Marsham, the Directors retiring by rotation, offer themselves for re-election. The auditor, Mr. Weise, retires, and is re-eligible.

The North Metropolitan Tramways Company (Limited).

The fortieth ordinary half-yearly general meeting of this Company was held at the Cannon-street Hotel on Wednesday, Mr. G. Richardson presiding.

The CHAIRMAN, in moving the adoption of the report, said he thought shareholders would agree with him that on the whole it was satisfactory. The accounts showed a total increase in receipts of £20,000. As a Company they had carried a large additional number of passengers, the aggregate for the year being 66,000,000. The penny fares had been a great success. There indeed had been such an increase in their traffic that they proposed to go to Parliament this year for power to increase their capital, with which to obtain the necessary additions to their rolling stock. In the same Bill power would be sought to apply electric or other mechanical traction over such portions of their system as they thought advisable. Complete success had attended their experiments with electric traction. Their installation of electric working indeed was the most successful in the kingdom so far, and they anticipated that the more general adoption of electricity would prove of great economic value. They had hitherto had to get power by a sort of licence from the Board of Trade. Now when the present Act expired, they would either have to get the power renewed or it would lapse, which would be regretable. They intended, as time went on, to adopt it on the various portions of their line that might be found suitable.

Mr. J. M. GILLIES seconded the adoption of the report.

Mr. JACKSON and other shareholders congratulated the Directors on the presentation of the best report they had yet laid before the proprietors. The first-named hoped there would be no difficulty in obtaining powers for utilising electric traction. There would be an economy of something like 20 per cent. In America there was ten times the amount of electric traction there was in this country.

Answering questions, the Chairman said the cost of electric traction was about 4½d. per mile, including drivers. The cost of horsing cars, without drivers, was 4·32d., and conductors, &c., might be put roughly at another penny a mile. The adoption of electricity would not, he thought, necessitate the relaying of their lines. All the lines they were now putting down were laid with heavy rails, such as were used in Barking-road, and wherever repairs were necessary the same metals were being used.

The report having been adopted, a dividend at the rate of 9¾ per cent. was declared, carrying forward £5,025 to the revenue account for the next half.

The retiring Directors and auditors having been re-elected, the meeting was declared special, when approval was expressed of the Bill the Board proposed to introduce into Parliament, the main objects of which the Chairman had already explained.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended January 31st amounted to £5,249.

CUBA SUBMARINE TELEGRAPH COMPANY.—The estimated traffic receipts of this Company for the month of January were £3,150, as compared with £3,221 in the corresponding month of last year. The receipts for the month of October, estimated at £2,900, realised £2,103.

DIRECT SPANISH TELEGRAPH COMPANY.—The traffic receipts of this Company for the month of January were £2,415, against £1,880 in the corresponding period of last year, an increase of £535.

EASTERN TELEGRAPH COMPANY.—The traffic receipts of this Company for the month of January amounted to £59,478, as against £65,835 in the corresponding period of 1889, a decrease of £6,357.

EASTERN EXTENSION, AUSTRALASIA, AND CHINA TELEGRAPH COMPANY.—The traffic receipts of this Company for the month of January 1890, amounted to £40,610, as compared with £41,820 in the corresponding period of 1889, a decrease of £1,210.

ELMORE'S PATENT COPPER-DEPOSITING COMPANY.—The secretary of this Company announces that the first section of the Company's works has been completed, and that the operations of manufacture have been successfully commenced. The Directors are arranging for an exhibit of the Company's manufactures in London.

GREAT NORTHERN TELEGRAPH COMPANY.—Messrs. Hambro and Son announce the numbers of this Company's debentures of 1833 (Series "B") drawn for payment on the 1st March.—The traffic returns of this Company for the month of January amounted to £19,600, against £22,400 and £21,400 in the corresponding months of 1889 and 1888.

THE UNION TRUST COMPANY OF NEW YORK.—This company notify that, in accordance with the provisions of the deed of trust executed by the Western Union Telegraph Company to the Union Trust Company of New York as trustees, 14 bonds, amounting to £2,100, have been drawn by lot for redemption on March 1st next at the offices of Messrs. Morton, Rose and Co., Bartholomew-lane, E.C.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended January 31st, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited), were £3,996.

WEST COAST OF AMERICA TELEGRAPH COMPANY.—The traffic receipts of this Company for the month ended January 31st amounted to £6,225.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The receipts of this Company for the half-month ended January 31st show an increase of £651 as compared with the corresponding period.

THE NON-CONDUCTOR OF ELECTRICITY.

WAREHOUSE.

VULCANISED FIBRE,

PATENTED.

This new material is supplied in two qualities, Flexible and Hard.

The FLEXIBLE is a substitute for Leather, Rubber, Gutta Percha, &c., and is extensively used by Brass Founders, Axle Makers, Hydraulic, Sanitary, and other Engineers, Pump Makers, Carriage Builders, &c.

It makes the best Hot and Cold Water Packings, and for Axle Washers of all kinds it is unequalled.

The HARD is a substitute for Metals, Hard Wood, Ivory, Vulcanite, Ebonite, &c., and is a good Insulator.

Sold in sheets, 5ft. 6in. by 3ft. 6in., varying in thickness from 1-50in. to 1in.

FLEXIBLE, 2/- per lb.; HARD, 2/3 per lb.

FACTORY.

JABLOCHKOFF'S
BISTRIBUTION PATENT

(Being a Patent for "Producing and Dividing Electric Light," No. 1996 of 1877.)

THE ELECTRICAL ENGINEERING CORPORATION (LIMITED)

Are Proprietors of the above Patent, and Warn the Public against Infringement.

The following are Licensees:—

Anglo-American Brush Electric Light Corporation, Limited.
Crompton & Co., Limited.
S. Z. de Ferranti.—London Electric Supply Corporation, Limited.
W. T. Goolden & Co.
Hammond & Co.
Wilson Hartnell.
Johnson & Phillips.
Laurence, Paris & Scott, Limited.
Nalder Brothers & Co.
Paterson & Cooper.
Ernest Scott & Co.
Siemens Brothers & Co., Limited.

3, Prince's Mansions, Victoria Street, Westminster, MANVILLE & MADGEN, *Managing Directors.*

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 613.—Vol. XXIV. FRIDAY, FEBRUARY 14, 1890. Price Fourpence.

NOTES.

The genuinely hearty vote of thanks which was accorded to Prof. Silvanus Thompson on Monday evening last at the close of his series of Cantor lectures on "The Electro-Magnet," together with the very large attendance throughout the course, were a sufficient proof that the efforts of the lecturer had been thoroughly appreciated. The electro-magnet, when treated historically, theoretically, and practically, is a somewhat unwieldly subject to deal with in the short space of four one-hour lectures; but so far as this difficult task could be accomplished it was accomplished. Mr. Preece, in proposing the vote of thanks, remarked that Prof. Thompson's classic lectures on "Dynamo-electric Machinery," delivered in the autumn of 1882, had been the forerunners of *the* standard work on the subject, and expressed a hope that a similar result would follow from the course of lectures on "The Electro-Magnet"—a hope which we have every reason to believe will shortly be realised. Prof. Thompson, it goes without saying, did what he could to rescue several already half-forgotten scientific worthies from unmerited oblivion. Sturgeon was duly installed in his niche as inventor of the electro-magnet, and Meran, the first to be inspired with the idea of the electric trembling bell, was not passed over. It also goes without saying that Prof. Thompson had some very severe remarks for his particular *bête noire* the text-book, with its fondness for archaic terms and exploded ideas.

The experience of the past eighteen months has very clearly shown that the Electric Lighting Act of 1882—that supreme effort of paternal legislation—is an eminently defective piece of machinery, and, indeed, but for the intervention of that *deus ex machina* the Board of Trade, it would be practically unworkable. In an article which will be found in another column the unsatisfactory condition of the law with regard to electric lighting is made tolerably apparent, and we can only hope that if the new Act for which Mr. Hayward calls is not within the region of practical politics, the Board of Trade will see its way to the adoption of some of his suggestions, notably those relating to the municipalities who profess their readiness to start electric lighting stations and fail to do so. Mr. Hayward emphasises, as we have more than once done, the confused state of the law with regard to electric inspectors as set forth in the Metropolitan Provisional Orders granted last Session. These functionaries, it will be remembered, are to be paid and appointed by one party, their fees are to be fixed by a second party, and they themselves are to be subject to the general approval of a third party—a condition of affairs by no means conducive to efficiency.

In our correspondence columns will be found a letter from Mr. H. J. S. Heather, expressing considerable scepticism as to the actuality of the figure (4½d. per car mile) at which the Electric Traction Company professes its readiness to work the whole system of the North Metropolitan Tramways Company. The incredulity of our correspondent may possibly be justified by the facts of the case, but a careful analysis of the figures relating to the Brussels tramways to which he refers does not altogether bear out his contention that the Traction Company's charge of 4½d. per car mile cannot be remunerative.

The cost of accumulator renewal at Brussels, M. Michelet states, was 1½d. per car mile (9 centimes per car kilometre), motor and gearing renewals amounting to about 1d. per car mile (5·74 centimes per car kilometre). The latter figure might well be reduced for English plants by 25 per cent., *i.e.*, to ¾d. per car mile. Again, while the Barking-road section is by no means an easy piece of road, the Brussels line, over which the Julien cars were run, is still less ideal. It must also be remembered that the cost of renewals is higher in Brussels than in London, and that the experience of the idiosyncrasies of accumulators gained by the Electric Traction Company in its preliminary experiments can scarcely have failed to have resulted in a material diminution of the renewal account. Taking these and other factors into consideration, 1¼d. per car mile would not now be an unreasonably low figure to allow for accumulator renewals. Making these deductions from the Brussels figures the Electric Traction Company have left 2½d. per car mile for steam power, wages, depreciation of stationary plant, miscellaneous expenses, and profit. That storage-battery traction cannot as a rule be so economical as a well-managed overhead system has always been our opinion. So long, however, as the sight of an overhead wire is an eyesore to our local authorities, accumulator cars, so soon as they have conclusively shown their superiority to horse cars, are likely to come into more general use than those which obtain their current from an external source.

A practical method of calibrating thermo-couples for high temperatures is described in the February number of the *Phil. Mag.*, by Carl Barus, who has investigated the varia-

Digitized by Google

tions caused in the boiling points of various metals by changes in external pressure. The result of these investigations, combined with the known boiling points of different metals at the atmospheric pressure, enables the calibration to be performed at all points over a very large range of temperatures. The apparatus for fusing the metals used in the experiments is described in detail. A platinum iridio-platinum thermo-couple was employed, the thermo-electric constants of which were measured, by a null method, in terms of the electromotive force of a LATIMER CLARK cell. It was, however, found best to use a torsion galvanometer, and to directly express the thermo-electromotive forces in terms of the twist of a platinum fibre. The instrument used was 135 cm. high, and when the needles of the galvanometer were strongly magnetised, it was found that a platinum wire 0·018 cm. in diameter was sufficiently thin. In order to avoid the error caused by the directive force of the earth's magnetism the needles were always brought back to zero by turning a torsion head at the top of the instrument. A mirror was attached to the needle, and a telescope and scale were employed to measure the fractions of a degree. A thermo-couple calibrated in this way should form an invaluable instrument for the measurement of high temperatures.

IN the same journal Prof. ERIC GERARD, of Liège, describes a process of plotting curves by the aid of photography. An induction coil is used to produce a spark between a strip of magnesium and a carbon point. This spark is thrown on a concave mirror, attached to a galvanometer-needle, and is thence reflected to the sensitised paper covering a rotating cylinder or other moving screen. A short white spark, invariable in position, is obtained by connecting the terminals of the secondary coil to the coatings of a Leyden jar. The breaks in the primary circuit are effected by means of a tuning fork, so that the successive spark photographs occur at regular known intervals of time. The error due to irregular movement of the scale is thus avoided, without the complication introduced by the usual method of taking a separate time curve. The method is illustrated by a photographed curve, showing the variations in the field of an electric motor. A short length of wire, fixed to the armature parallel to the axis, is connected by suitable collectors with a galvanometer whose moving parts have little inertia. The lateral displacement of the photographed spark then measures the strength of the induced current, while its number represents the time.

M. LEDUC has recently shown that the alteration in resistance which bismuth undergoes when placed in a magnetic field varies considerably with the temperature of experiment. An analogous influence of heat occurs in HALL'S phenomenon. The intensity of the magnetic fields used varied up to 9,000 C.-G.-S. lines per square centimetre. M. LEDUC finds that, for temperatures between 0°C. and 45°C., the alteration produced by imposing a field of 7,000 lines diminishes by 1·09 per cent. for every degree centigrade increase in temperature.

THE Deptford station has been the subject of many adverse comments, but it has remained for the *City Leader* to prove, with all the precision of a geometrical demonstration, that the scheme is hopeless. "It is a law of electrostatics," says the *City Leader*, "that the resistance to an electric current is proportionate to the length of the conductor and inversely proportionate to its transverse section. The conductor employed by the London company to bring current from Deptford is described as a hollow tube. If that is so, there can be no compensation of transverse section as a set-off to the tremendous resistance of the length of the cable." The short-circuit (*sic*) system of the Metropolitan company is, according to our contemporary, the solution of the problem.

An Electrical Inspector for Dublin.—The Corporation has decided to appoint an electrical inspector at £200 a year.

Croydon.—The Corporation has decided to oppose the Order promoted by the South of England House-to-House Electricity Company.

Northampton.—The Town Council has given formal consent to the Provisional Order of the Northampton Electric Light Company.

Ozokerite.—During 1889, the product of ozokerite from the Utah mines was approximately 130,000lb., as compared with 65,000lb. in 1888.

Obituary.—The death of Mr. Alfred Cowles, the inventor of the Cowles electric furnace for the production of aluminium, is announced from Chicago.

Hornsey Local Board.—At the last meeting of this Board it was decided to oppose the Order promoted by the House-to-House Electric Light Supply Company.

The French Atlantic Cable.—The cable steamer "Mackay Bennett" has successfully completed the repairs to the English-Brest section of the French Atlantic cable.

Electric Traction in Holland.—The first electric tramway in Holland will be opened in March next. It runs from the Hague to Scheveningen, a distance of about four miles.

Southport.—The Gas Committee of the Southport Corporation have refused an application for permission to run overhead electric light wires over certain streets in the centre of the town.

Electro-Therapeutics.—A series of articles by Dr. Arthur Harries and Mr. H. Newman Lawrence, entitled "Practical Lessons in Electro-Therapeutics," is being published in the *Nursing Record*.

Heriot-Watt College, Edinburgh.—At a meeting held on Monday of George Heriot's trustees, Dr. R. M. Walmsley, of London, was appointed Professor of Electrical Engineering in this College.

Edinburgh Exhibition.—Messrs. Galloways have been requested by the Executive Council of the Exhibition to provide the steam required, and have agreed to supply five "Galloway" boilers, 30ft. by 8ft., for that purpose.

The Llanerch Pit.—While we sincerely deplore the awful loss of life which occurred at the recent explosion in this pit, we are glad to learn that Messrs. Immisch and Co.'s 30 horse-power pumping and hauling plant was quite uninjured.

The Electric Lighting of the British Museum.—The grand total of visitors to the Museum in the first six working days of its evening opening was 12,228, or nearly one-half as many as visited the Museum during the whole of the preceding month of January.

St. George's (Hanover-square) Vestry.—At the last meeting of this vestry the recommendation of the Electric Lighting Committee that the vestry should give their consent to the application of the Chelsea Electricity Supply Company for a Provisional Order and a licence, was adopted.

Wimbledon Local Board.—At the last meeting of the Board the Electric Light Committee reported that Mr. Preece had laid before them estimates of the cost of lighting the town with electricity, which estimates had been ordered to be printed, and placed in the hands of the members.

Digitized by Google

Tunbridge Wells.—At the last meeting of the Town Council the Electric Lighting Committee presented a report on the Provisional Order promoted by the South of England House-to-House Electricity Company, and objections which they had lodged with the Board of Trade against it. The report was adopted.

South African Telegraphy.—The Cape Government has authorised the construction of a direct line from Potchefstroom to Vredefort over Venterskroom. Eight wires will be added to the line from Potchefstroom to Klerksdorp, and four wires to the line from Klerksdorp *viâ* Wolmaranstad, Bloemkof, and Christiana, to Kimberley.

Fulham Vestry.—This Vestry has decided to oppose the Provisional Orders of the House-to-House Company and the Brush Electrical Engineering Corporation on the ground that there in not at present sufficient demand for the light to justify the expenditure of capital and the disturbance of the streets which would result from approval.

The Transformer Patents in Austria-Hungary.—The action brought by Max Deri, engineer to Messrs. Ganz and Co., of Budapest, for the revocation of the Gaulard-Gibbs patent for the distribution of electricity by means of transformers, has been successful, and their patent of December 27th, 1882, has been annulled on the ground of anticipation and too broad a claim.

The Value of the Ohm.—M. Wuilleumier has recently conducted a series of experiments, by M. Lippmann's method, to determine the true value of the ohm. He found that it was equal to the resistance of a column of mercury at 0°C., 1 square mm. cross section, and 106·27 centimetres high. This value differs by 1/5000th from the values adopted in 1881 and 1884.

Actino-Electric Phenomena.—J. Borgmann has recently shown by illuminating the anode through a rotating perforated disc and observing the current by means of a telephone, that the action of the ultra-violet rays is not instantaneous but requires an appreciable time. In fact, the telephone clearly indicated a current when the disc was at rest and the anode was illuminated, but the sound ceased when the disc revolved.

Industrial Enterprise in Hungary.—In the Lower House of the Hungarian Diet on Saturday last, the Minister of Commerce, M. Baross, presented a Bill, with the object of fostering home industries. It provides that factories which make articles not hitherto produced in Hungary, and many already existing concerns which the Minister specified, including machine and electrical works, shall enjoy exemption from income-tax, besides other advantages.

Electrostatic Phenomena in Ceresin Works.—In a stearin and ceresin works in Italy it was recently discovered that ceresin presents some remarkable electrical phenomena. The electric light went out suddenly one evening, and it was found that some small casks of white hard ceresin, which had been set aside to cool, and were then just at the solidifying point, gave off pale sparks at the slightest movement, and gave the hand a shock at 1·6in. distance. These phenomena lasted half an hour.

Oyonnax.—MM. Cuenod-Sautter, of Geneva, are erecting a hydro-electric generating station close to a large waterfall, eight kilometres from Oyonnax (Ain). The generating plant will at first consist only of two 150 horse-power dynamos. As the district is a manufacturing one, the current will be used as much for motive power as for light. This installation is expected to attain some importance in the near future, and arrangements are being made for an ultimate capacity of 1,200 horse-power.

Weybridge.—At a recent meeting of the vestry a report by Major Cardew was read, which stated that the present overhead wiring was not in accordance with the Board's regulations for high-pressure service as regards the insulating covering. To comply with these regulations would, it was stated on behalf of the contractors, involve an expenditure of £400 to £500. After some discussion, it was decided to make arrangements for placing the conductors underground, as soon as the experimental lighting had been fairly tried.

The Société Générale des Téléphones.—The Directors of this Company in their last report to the shareholders state that the telephone manufacturing business of the Company has increased so much of late that it has been found necessary to greatly extend the Paris factory. The Directors also announce that it is their intention to add a submarine cable department to their factory at Bezons. One half (59 miles) of the cable between Martinique and Guadeloupe, recently laid by the Compagnie Française des Télégraphes Sous-Marins, came from the Bezons works.

Proposed Electric Railway between St. Petersburg and Archangel.—*La Lumière Electrique* reports that a scheme is on foot in Russia for connecting Archangel and St Petersburg by an electric railway. The estimated cost of the proposed line, including rolling stock, is £4,150 per mile, or 30 per cent. less than that of an ordinary railway. As the distance between Archangel and St. Petersburg is considerably over 500 miles as the crow flies, the Archangel merchants, who are said to have originated this project, must possess a remarkable degree of enterprise.

The Institution of Electrical Engineers.—The students of the Institution met last Friday to discuss Mr. Mordey's Paper on "Alternate Current Working," Mr. W. B. Esson in the chair. The meeting first confirmed the election of the following committee for 1890:—Messrs. A. E. Childs, S. L. Horn, J. A. Muir, G. Müller, G. H. Thornton, H. Walker, D. S. Barton, hon. sec. Mr. Müller then made some opening remarks on the above Paper, and the discussion was continued by the Chairman, Messrs. Wightman, Walker, Horn, and Raphael. A vote of thanks to the Chairman terminated the proceedings.

Colonial Telegraphic Statistics.—

Total Mileage of Telegraph Lines Open.

	1879.	1888.	Increase.

The Surgical Electric Lamp.—In a short article on "The History and Uses of the Protected Surgical Electric Lamp," in a recent number of the *British Medical Journal*, Mr. N. Stevenson states that in 1883 he designed an electric light for dental work, but the difficulty in getting the lamps and unsatisfactory working of the batteries made him abandon the use of it. Now, however, that better lamps can be easily obtained and that the batteries are immensely superior to the old ones, he had taken to them again and adapted them to other surgical purposes. "I cannot," says Mr. Stevenson in conclusion, "estimate the practical value to others of these instruments, but I think there must be many who will find them, as I do, of great service."

Telegraphic Wire Boxes and Gas Leakages.—The postal authorities at Barnsley have been annoyed for some little time by escapes of gas in the "flush" boxes which contain the underground telegraphic wires; and the *employés* of the Barnsley Gas Company have been endeavouring to discover the causes of the escapes, and have tested the boxes frequently. On Thursday last week one of the men tried a box by striking a match. Immediately a loud explosion occurred. The man had a remarkable escape, being injured in the face by a piece of stone. The shock was felt a considerable distance away, whilst it blew the covering of the box (weighing about 1 cwt.) into the air, and it fell at a distance of fully fifty yards.

Electrical Phenomena in Nature.—Electrical phenomena in nature formed the subject of an interesting lecture delivered at the London Institution on Monday afternoon by Mr. Shelford Bidwell, who dealt with the question chiefly as it related to thunderstorms. Mr. Bidwell said that the lightning flash made familiar by artists was not known to science, and was about as truthful as most attempts to depict horses in motion. Referring

Digitized by Google

to the controversy initiated by Dr. Lodge as to the value of electrical conductors, the lecturer said that in all cases of "steady strain" a lightning conductor was of great service, yet it could not always be relied upon as affording immunity from risk. As to the danger to life from lightning, one was almost as likely to be hanged for murder as to be killed by lightning.

St. Pancras Vestry.—On Wednesday the St. Pancras Vestry decided, in accordance with a recommendation of the Electricity Committee, to pay Dr. Hopkinson, F.R.S., 100 guineas in consideration of the Committee and Prof. Robinson being at liberty to consult him from time to time on the details of the installation and preparation of plans, specifications, and estimates for carrying out the same up to the time of advertising for tenders. Messrs. Bircham and Co., Parliamentary agents to the Metropolitan Electric Lighting Company, intimated the desire of this Company to supply the south end of Tottenham Court-road, and asked for the Vestry's authority to lay their mains across that part of St. Pancras. The request was not complied with, as the Committee "considered it undesirable to allow a Company to have any powers in the parish."

A Carbonic Oxide Indicator.—An apparatus for indicating the presence of carbonic oxide gas in the atmosphere has been perfected by a M. Rasine. Its action depends on the property of spongy platinum to absorb carbonic oxide with evolution of sensible heat. Two metallic plates are placed vertically over each other, which when touching close an electric circuit. The upper plate is suspended from a hook by means of an easily combustible thread. This thread is wrapped in muslin, containing a little cotton powder dusted over with spongy platinum. If this arrangement is exposed in an atmosphere containing carbonic oxide, the spongy platinum will absorb it, and set fire to the cotton, which will in turn burn the thread, and so cause the electrical contacts to complete the circuit, and ring a bell. It remains to be seen whether the spongy platinum would always remain good for use in this way, and also that the same effect would not be produced by any other gas to which the apparatus would be exposed.

The Municipal Rapid Transit Problem in London.—Speaking recently in support of the Central London Railway scheme at the City Tradesmen's Club, Mr. William Morris (of Ashurst, Morris, Crisp and Co., solicitors for the Bill), gave some interesting figures with regard to the increase in the number of passengers carried by the various companies within the metropolis. In the year 1864 the number of passengers carried by the London General Omnibus Company, the Metropolitan Railway, the District Railway, and the tramways combined was 53,000,000; while last year the London General Omnibus Company carried about 80,000,000, the Metropolitan Railway and the District Company combined about 120,000,000, and the tramways 130,000,000: a total of 330,000,000, or an increase of over 600 per cent. During the same period the population of the metropolis had only increased 40 per cent. Those four companies carried every person in the population 90 times in the year, while in New York every person in the population was carried something like 200 times.

Bradford.—In moving the adoption of the proceedings of the Gas and Electricity Supply Committee at the last meeting of the Corporation, Alderman Priestman, referring to the electric light, said that the expenditure to the end of the year was £26,013, but as the works were not in operation till November 1st, there had only been two months in which electricity was supplied, and the income during that time was £580. Until the works had been in operation a few months longer, a definite idea could not be formed as to the financial result; but he had every confidence in the success of the electric works, and the Town Clerk had had an offer from a gentleman to give the Corporation a profit of £10,000 if they would put the works into the market. Replying to Mr. Galloway, who expressed a fear that the electric works would not prove profitable, he added that he had no doubt that next year he would be able to give a satisfactory statement, although he did not expect he would be able to show a profit till the end of two years. At the same time, he pointed out that the main object of the Corporation in undertaking to supply electricity was to keep out other persons who were offering to provide the electric light for towns.

The Jacobus Closed Circuit Burglar Alarm.—In a recent number of the *Stevens Indicator*, Prof. W. S. Jacobus, of the Stevens Institute of Technology, describes a new form of closed circuit burglar alarm. The trouble experienced in connection with a closed circuit system with gravity batteries, led to the adoption of what is nothing more than a high resistance galvanometer furnished with a means of making and breaking a powerful supplementary circuit containing the alarm bell, the main circuit current being provided by a single Leclanché cell. The resistance of the galvanometer is about 2,600 ohms, so that this single cell may be expected to run three or four years without renewal. The supplementary circuit is actuated as follows. On the top of the needle at the centre is attached a bent platinum wire, dipping into a trough of mercury. Underneath the needle at some distance from its centre there is a projecting platinum stud, and underneath this again there is a nearly complete circular groove filled with mercury. Each mercury trough is in connection with one end of the supplementary circuit. When the main current is flowing through the coil of the galvanometer the projecting platinum stud is situated midway between the two ends of the nearly complete circular groove. When the current ceases the needle swings over, the platinum stud enters the mercury, completing the supplementary circuit and ringing the alarm bell.

The Conductivity of Coloured Flames.—Several attempts have been made to measure the conductivity of flames, and especially of those containing the vapour of metallic salts. These investigations have up to the present only furnished contradictory results. To obtain coloured flames under definite conditions Wiedemann and Ebert have, by means of a spray, impregnated the air feeding a Bunsen burner with a saline solution of suitable density, and have thus been in a position to know exactly how many milligrammes of metallic vapour were contained at any moment in a unit volume of flame. The character of an electric discharge is, of course, considerably modified by interposing a flame in its path: the discharges become more rapid and the sound given out by a telephone is increased. On the introduction of metallic vapours into the flame, a still further change takes place, the nature of which essentially depends on the nature of the metal introduced. With potassium the telephone is reduced to silence, the discharge becoming almost continuous. Sodium, even in considerable quantities, produces a far smaller effect. In both instances the discharge remains disruptive in character, and there can, therefore, be no question of the flame being electrically conducting. Potassium and magnesium have peculiarly strong effects, due doubtless to the ultra-violet rays which they emit in abundance, and the effect of which when they fall upon the negative electrode is to lower the difference of potential necessary to cause a discharge.

Frosting Incandescent Lamp Bulbs.—All the portable incandescent lamps used on the Pullman special trains have frosted or "ground" bulbs, prepared in the glass department of the Pullman Car Works by suspending the glass bulb in a solution of so called "white acid" till the proper depth of glass is removed or dissolved. Mr. A. H. Bauer has suggested the employment of the Planté process for securing delicate tracings on the lamps, and, in fact, on all the glass so treated, namely, to cover the plate with a saturated solution of nitrate of potassium (pure saltpetre), and trace the design thereon with a finely-pointed platinum pencil connected to one pole of a storage battery, the other pole being connected to the plate. The white acid can be prepared by slowly mixing equal parts of hydrofluoric acid and soft water in a lead or rubber vessel, and allowing same to stand till cool. (Add the acid to the water, not the reverse.) Then carefully drop small particles of carbonate of ammonia into the solution till all foaming ceases, when the solution is ready for use. In using the preparation it is well to preserve the fingers from ill effects by anointing them with vaseline or some similar preparation. Another method of securing a temporary frosting on a globe, and one more simple and easy of operation, is to make a saturated solution of sulphate of magnesia (Epsom salts) in clear water; strain the solution to remove any minute particles of dirt, and then dip the bulbs therein, drying and dipping again, repeating the

Digitized by Google

process two or three times till the desired effect is secured. But bulbs thus coated can only be used on one or two occasions, and must be handled with extreme care. The frosting can be entirely removed by a moment's washing, thus leaving the glass clear for treatment with tints or otherwise.

Brighton.—On Friday evening last a public meeting was held for the purpose of passing a resolution to the effect that the proposed municipal electric lighting scheme was an experimental one, and must necessitate the expenditure of a much larger sum than £30,000. There was a very large attendance. Councillor Ballard presided, and amongst those present on the platform were Mr. Killingworth Hedges, Mr. F. Ince, Mr. Mark Parker, of Rochester, and Mr. W. T. Taylor, of Harrow-on-the-Hill. The chairman said that the whole proceedings in connection with this electric lighting scheme had been characterised by undue haste, and the vote in favour of it had only been carried owing to the fact that many members had given their votes under the erroneous impression that a private company would have a monopoly and practically unlimited powers of disturbing the streets. Electricity was, in his opinion, a luxury, and should not be supplied at the ratepayers' expense. Mr. Killingworth Hedges criticised Mr. Shoolbred's report, especially from the financial point of view, and asserted that it would be impossible to make both ends meet if only 6d. a unit was charged. He then detailed the advantages of the high-tension alternate-current system, and said that perhaps the best testimony in its favour was its rapid progress in America and its adoption at Paris and Rome. Mr. F. Ince laid great emphasis on the inevitable expense attending the multiplication of generating centres, and said that according to Mr. Shoolbred's plan Brighton would require from 37 to 40 stations. He advocated one large station and 10,000 light dynamos. The resolution was subsequently carried with the addition of an amendment requesting the Mayor to call a public meeting to consider the question.

Mr. Edison and his Work.—In the February number of *Harper's Magazine* there is an article by Mr. George Parsons Lathrop, a well known *littérateur*, giving the gist of several conversations he has had from time to time with Mr. Edison. One point may be noted in connection with the incandescent lamp—in regard to the immense amount of work done by the inventor before he obtained what he considered satisfactory results in connection with the lamp and its filament. Mr. Edison stated that from first to last he had constructed some 3,000 different theories in connection with the electric light, each one of them reasonable, and apparently likely to be true; yet in only two cases did his experiments prove the truth of his theory. Mr. Edison stated further that his work is still going on with the lamp, and that he had now reached a point where he could maintain fully 15 lamps to the horse-power. The article does not mention the fact, but it may be noted that at the present time Mr. Edison is actively engaged with his magnetic ore separator, with which some very good results have lately been obtained. He is also very busy with the development of some new ideas in connection with electric traction, his aim being to perfect a method by which electric cars can be run in cities with direct supply, but without the objectionable features of the overhead wire system and of the conduit system. It is believed that Mr. Edison himself will take an active part in the further development of the Sprague Company, both as regards electric traction and as regards stationary motor work. Another matter to which Mr. Edison is giving some of his attention, it is said, is the equipment of the new Edison stations in this city, including one which, if report be true, will be equipped with large Edison multipolar generators of new design, coupled direct to compound condensing engines.

The Mehner Dry Cell.—An improved dry cell has recently been brought out by Dr. C. H. Mehner, of Berlin. In dry cells it is usual to employ as a vehicle for the exciting liquid a neutral material which absorbs the liquid excitant and forms therewith a stiff paste. The materials commonly employed for this purpose are sponge, sawdust, gypsum, gelatine, and the like. It is evident that the introduction of these inactive materials is prejudicial to the action of the cell, as they form an encumbrance which, apart from its purely mechanical action, in no way promotes, but on the contrary tends to diminish, the effective working of the battery. In order to dispense with this inactive matter, Dr. Mehner imparts the required consistency to the exciting agent by preparing it as follows:—The exciting salts, consisting of suitable chlorides of the alkalies, are mixed with a "mineral gelatine." This gelatine retains the salts in a paste, and, possessing exciting properties in itself, also acts as an exciting agent. The "mineral gelatine" consists of crystallised hydrated basic chloride of magnesium, which is formed by the addition of magnesia to a highly supersaturated and concentrated solution of magnesium chloride. If a suitable quantity of the solution of magnesium chloride is added to the oxide of magnesia, for example, in the first instance, a liquid product of a creamy consistency results, at first gradually gelatinising and ultimately acquiring a pasty consistency. The degree of stiffness of the final product can be readily controlled by suitably regulating the addition of chloride solution. Dr. Mehner utilises this property of oxy-chloride of magnesium in the preparation of his dry cell. He stirs the exciting salt with a solution of chloride of magnesium and calcined magnesia until he obtains a liquid of about the thickness of cream, which he pours into the cell. In the course of a few days the liquid changes to a stiff pulp, and the cell can then be closed. The "mineral gelatine" being in itself a substance capable of producing an exciting action in a galvanic cell, the employment of an inactive material is thus entirely obviated.

Effect of a Thunderstorm upon an Underground Endless Rope at Kibblesworth Colliery.—The December number of the *Journal* of the British Society of Mining Students contains an interesting account of a curious electrical phenomenon which was observed at the Kibblesworth Colliery, on July 23rd, during a sharp thunderstorm. The phenomenon occurred in connection with a self-acting endless rope 1,900 yards long, situated in what is known as the Hutton Seam 60 fathoms below the surface. The rope affected by the storm was not connected with any other rope: it was of 2½in. iron and had tubs attached to it at intervals of 25 yards. During the thunderstorm the rope became suddenly charged with electricity. The lad "braking" said that at about 2.15 p.m.: he felt "strange sensations" in his right hand, which was on the brake handle, and also in his legs. The shocks were intermittent, and only slight at first, so that he was able to touch the brake or rope when necessary. In a few minutes, however, the rope gradually slackened its speed, and then stopped. This stoppage was apparently accounted for by a full tub being found off the way. The waggon-way man, who had charge of the ropes, lifted this tub on to the rails with the assistance of the brake lad: they both received several shocks whilst handling the tub, they then immediately went into the brake wheel expecting that the rope would go away on lifting the brake. The rope, however, would not move. They then called another man and some lads and "swayed" on it for nearly a quarter of an hour. It then moved a yard only and stopped again. Subsequently another full tub was found "ended up" on the rails. They replaced this tub and again felt electric shocks on taking hold of the tub. After again working at the rope for about a quarter of an hour with no result, they all desisted, and then whilst considering what to try next, within five minutes, when no one was touching the rope, it gently moved away as if nothing had been wrong, and continued to run in the ordinary way, without giving any more trouble, for the remainder of the day. The time was 3:45 p.m. when the rope began to run again, and by this time the thunderstorm was also about over, and no more shocks were received from either rope or tubs. Altogether 11 men and boys received shocks. Electric bells are used on this road for signalling, in addition to the telephone: they all worked correctly during the electrical disturbance. The endless rope hauling to the shaft was not in any way affected. No lightning was seen by any one in the pit. This seems to show that the electric current did not descend by the shaft, but more probably was produced in the rope by induction from the earth on its becoming highly charged with electricity at the commencement of the thunderstorm.

ELECTRICITY AND THE LAW.

BY A. C. CURTIS HAYWARD, B.A.

No one who has followed the course of events during the past twelve months, or has glanced at the list of applications to the Board of Trade for electric lighting powers recently printed in these columns, can fail to recognise the great and increasing importance of the attitude of the law towards electrical industry. No apology need therefore be made for referring to this subject at some length.

We shall not discuss the vexed question whether electricians of to-day or the general public are in any respects the better for the Act of 1882, which resolves itself principally into the inquiry whether it was desirable at that date to snuff out the flame of perhaps too sanguine speculation. We have to deal with the law as we find it now, and certainly an examination of this Act does not lead to the opinion that it is anything to be proud of as a piece of legislation. So long as the famous 27th Section stood, it mattered very little what else there was or was not in the Act; but directly this stumbling block had been removed, and 42 years were substituted for 21, within which capitalists might reap the reward of their expenditure, the rest of the Act at once demanded attention. It then became apparent what a defective and incongruous piece of patchwork had been hastily put together. The primary object being, as was supposed, to enable undertakers to break up streets for laying their conductors, it is remarkable that no such power is to be found within the four corners of the Act. Certain things are stated to be forbidden or permitted in case of streets being broken up, but the power itself and the general regulations under which it may be exercised have to be sought for in certain sections of the Gas Works Clauses Acts, which are incorporated and adapted for the purpose by the rough-and-ready direction "for 'gas' read 'electricity.'" Anything seems at that date to have been thought good enough for the new infant "electricity," and it must needs make shift with old clothes, principally belonging to its elder brother "gas," until new clothes could be provided for it—which, truth to tell, no one knew exactly how to make. In the meantime fresh light was thrown upon the nature of electricity by a Parliamentary enactment, which provided, amongst other things, "for the washings and waste liquids to arise in the course of its manufacture." If the use of "scrubbers" had also been prescribed, this would doubtless have been considered no more than was proper for the infant's health.

To the Board of Trade was entrusted the duty of providing the new garments, and such were the materials that department had to work upon when the wave of enterprise which had been beaten back in 1882 again advanced in 1889, and for the first time serious business had to be dealt with under the Electric Lighting Acts. A drastic remedy was clearly necessary, and the Board wisely made no attempt to patch up the rags of existing legislation, but by the issue of their model form of Provisional Order practically enacted an entirely new law, which to a great extent supersedes the Acts previously in force. This was so far good, and was effective as regards Provisional Orders, which, being confirmed by Parliament, become statutory enactments. But how does the case stand with respect to Licences, which the Board of Trade desired should be subject to the same law as Provisional Orders? The Act of 1882 gives prospective sanction to regulations on various subjects to be inserted in Licences by the Board of Trade, who have very wide powers in this respect. These powers are not, however, wide enough to admit provisions which are inconsistent with the Acts, or which deal with subjects not expressly committed to the discretion of the Board. Consequently, clauses about which no questions can arise, if sanctioned by the confirming Act that gives validity to a Provisional Order, might be *ultra vires* if resting on the mere authority of a Board of Trade Licence.

An instance of this difficulty was noticed a few months ago in these columns in connection with a Licence for Newcastle. The particular case in question is not, that we are aware of, pointed out in any legal treatise, and the right of its discovery appears, therefore, to be the exclusive property of the Town Clerk of that city. The Act of 1882 authorises the Board of Trade to impose penalties in various cases, and such penalties are provided for in the Model Order, which goes on to say that these may be recovered in a summary manner before a Court of Summary Jurisdiction. Unfortunately, this addition is not authorised by the Act, and needs confirmation by Parliament; so that defaulting licencees, although they might suffer under the stigma of being legally liable to penalties, must go scot-free in the absence of a Court empowered to order payment. The validity of some other clauses of the Model Order must also be open to doubt when applied to Licences, so that for this reason, if for no other, the Electric Lighting Acts calls for some immediate amendment.

Other reasons are not, however, wanting. The Model Order is a very lengthy document, nearly the whole of which is occupied with matters of general application, which ought not to be repeated in every Licence and Provisional Order, thus entailing useless labour upon everybody concerned. It has already been announced that pressure of electric lighting business has necessitated some changes in the staff of the Board of Trade. We suggest one contribution towards relieving the labour of that Department: it is that the law should speedily be placed on a sounder basis. The infant has now grown to years of discretion, and is big enough to be relieved from the temporary assistance of Acts framed for totally different purposes. In a word, if a new Act is to be passed, it should not be a mere tinkering at the present defective structure. The two Electric Lighting Acts should be repealed, such of their sections as are not obsolete being re-enacted in an Electrical Works Clauses Act, which could deal comprehensively with the whole subject in a businesslike manner, and avoid the necessity for the same provisions being re-enacted over and over again in every Provisional Order.

There is further reason for putting forward this suggestion at the present time. Nothing but a general Act can remove the inconvenience and difficulties likely to arise from the anomalous position occupied by the London County Council under the Metropolitan Orders granted in 1889. It is very desirable that the serious mistake which has been committed in this respect should be rectified before its effects have become stereotyped. We use the term "anomalous" advisedly, because there is nothing in the previous state of the law which gave any countenance to the position claimed by the Council, and which has to some extent been conceded to their demands. It is true that the Provisional Orders which make these concessions have, as a matter of fact, been confirmed by Parliament, but this does not justify the inference that the very important departure from the policy of the Electric Lighting Acts thereby inaugurated has been deliberately adopted by the Legislature. It is well known that some important questions were allowed to slide by the companies directly interested, rather than, by raising objections at a late period of last session, run the risk of having their Orders shelved for another year. The companies may also have secretly solaced themselves with the belief that certain objectionable clauses would be found unworkable, and so die a natural death without being attacked. Had such an attack been made, we cannot believe that these mischievous provisions would have become law.

We have already pointed out that, in framing the Electric Lighting Act of 1882, Parliament was either unable or unwilling to deal effectively with the whole subject, and preferred to throw upon the Board of Trade all the responsibility of filling in the details to a mere outline hastily sketched by that Act, subject to certain reservations in favour of the Local Authority of each district. It is not our present purpose to quarrel with this policy, but merely to affirm that responsibility and control should remain in the hands to which the Legislature committed it. The very important functions to be performed by "electric inspectors" as regards testing mains, &c., should, we think, have been exercised only under the direct control of the Board of Trade; but in any case such control should not have been committed to the London County Council. This objection is accentuated by the expectant attitude of that somewhat over-zealous body, who seem to anticipate their acquirement of other powers from the Board of Trade. We have had only too

Digitized by Google

many recent instances of the audacious ignorance or wilful misrepresentation of those who aspire to guide public opinion on electrical matters in the daily press or in contributions to monthly reviews. It must therefore be a subject of anxiety to those interested in the progress of electric lighting, that while the public mind is thus kept in a condition of unstable equilibrium, the first step should have been taken towards allowing interference in technical matters by a popular assembly, which is without experience and without machinery such as is possessed by the Board of Trade, and which must always be exposed to the influence of popular panic or unscrupulous agitation. Moreover, there is the special objection to the London County Council that it has no official status under the Electric Lighting Acts, except as regards such parts of the Metropolis as the late Metropolitan Board of Works were authorised to light, and for which it has now become the Local Authority. As regards the far larger area which is under the jurisdiction of parochial authorities, the Council is a body altogether unknown to the Acts, and its status under the Model Order is therefore the gratuitous creation of the Board of Trade. If, as is surmised by Major Marindin in his report, the Council should ultimately become the central authority for the purpose of lighting and managing the streets of the whole Metropolis, it will no doubt also become the Local Authority, as defined by the Act, for the same area, and then will be time enough to consider what, if any, new functions it shall exercise in connection with electric lighting. But in the meantime the grant of any special powers to the Council is merely introducing a system of dual government which, we are always being told, is just what London does not want.

As matters now stand, the result is certainly somewhat confusing, and anyone reading the Model Order must be a good deal puzzled by a kind of kaleidoscope effect produced by the frequent changes between the names "Local Authority" and "County Council," of which the guiding principle is not always easy to deduce. For instance, with the object presumably of preserving the strict impartiality of the "Electric Inspector," he is parcelled out with great care between these two authorities and the Board of Trade. He is to be appointed by the London County Council, who are also to fix and pay his remuneration; his fees for testing mains are to be fixed by the Local Authority, subject to the approval of the Board of Trade. His fees for certifying meters are, however, to be fixed, not by the Local Authority, but by the County Council, who may also require him to hand over all fees he may receive to the county rate. Finally, if the Council do not appoint an Inspector, the Board of Trade may do so. We might suggest one addition to all this, namely, that if any of the parties should not be satisfied with their share in the electric Inspector, he shall be re-alloted by an arbitrator.

There is another point which has already provoked discussion both in these pages and elsewhere, but since it is somewhat of a burning question we may be pardoned for mentioning it again. The Board of Trade, by No. 2 of their rules relating to applications for Provisional Orders, &c., have laid down that they "will give preference to the application of the Local Authority of the district in every case where, in the opinion of the Board of Trade, *no special circumstances exist which render such a preference inexpedient.*" Now, it might be thought unfair to say that this rule—which, we are bound to admit, is not inconsistent with the spirit of the Electric Lighting Acts—should be wholly repealed, because certain Local Authorities have made use of the advantage it accords in a manner which cannot have been intended by its framers. We have as yet no experience as to what circumstances will be deemed by the Board of Trade so special as to forfeit the right of preference, and our remarks may therefore be only anticipating some effectual remedy which has already been determined on. We certainly do hope that there is stored up somewhere in the official mind an appropriate Nemesis ready to descend at the right moment upon those who have been guilty of abusing their privileges. We venture further to hope that the form of this Nemesis will also shortly be made public, so that it may be duly digested before the 1st July comes round again. In the meantime we trust it will not be thought disrespectful if we express an opinion as to the construction of a rule whose administration is solely within the province of the Board of Trade. Personally we should not regret if a radical amendment were adopted, but for the present we content ourselves with an interpretation of the rule as it stands. We should ourselves think *such a preference inexpedient* in any case where the Local Authority applying for a Provisional Order had on a former occasion been instrumental in stifling an independent application, without any *bonâ fide* intention of itself obtaining lighting powers. We should find the Local Authority guilty of this act of infanticide if it had—say within two years previously—passed a resolution, in the manner prescribed by the Act of 1882, that lighting powers should be applied for, and had failed to make such application in the following month of November; or had withdrawn its application without being able to satisfy the Board of Trade, after hearing anything alleged to the contrary by an opposing applicant, that such failure or withdrawal was due to good and sufficient causes not existing at the date of the resolution. We need hardly say that we should not consider a sudden aversion to electric light, or a discovery that it would be detrimental to the Corporation gas works, a good or sufficient cause. We further suggest that it might be a useful addition to the rule to make it one of the conditions of preference that the Local Authority should have lodged with its memorial of application a statutory declaration made in such form and manner as the Board of Trade should prescribe, giving assurances of a *bonâ fide* intention to prosecute the application. There remains, of course, the possibility of a Local Authority obtaining a Provisional Order and making no effective use of it. This is to some extent enhanced by the fact that, judging by the Order granted last year to the Swansea Corporation, no security will be required by the Board of Trade from Local Authorities, such as other undertakers are required to give for performance of their obligations as regards laying mains. In such a case, however, the Board of Trade would probably not be slow in granting powers to a competitor.

It would not fall within our limits to add more at present as to defects in the law of electric lighting, but we hope enough has been said to make out a case for its reconsideration at an early date.

UNDERGROUND MAINS.

BY G. L. ADDENBROOKE.

V.

(Continued from page 344.)

HOUSE-TO-HOUSE COMPANY.

The best example of the underground system of conduits and mains used by this company is furnished by the arrangements adopted in their exceedingly neat and well-arranged alternating-current station at West Brompton. This station has now been working nearly a year, and has been extending its operations rapidly since the Board of Trade permits were issued in October last. The pressure used is 2,000 volts, and the underground system is on the same lines as that in the well-known pioneer installation at Eastbourne, which has worked so satisfactorily since its establishment.

The mains are all of indiarubber-covered wire, manufactured by the Indiarubber Company of Silvertown. The insulation is their highest class of vulcanised rubber, and this is protected by a double braiding saturated with compound. This is a class of cable which has proved its ability to confine a 2,000 volt current to the conductor, in several instances for long periods, in a perfectly efficient manner. The connections for customers are made by opening the cables and splicing in smaller wires, the place of opening being insulated again in the ordinary manner of making a first-class rubber joint. The largest sized cable at present in use is 19/17, and from this they range downwards to the small size used for connecting customers.

These cables are all laid in iron piping with a system of manholes and connecting boxes which have been specially designed for the work. The company find that they can draw as great a length as half a mile of cable in at once quite easily,

Digitized by Google

even round corners if necessary, by taking the precaution to station a man at each manhole to ease the cable, and to pass it round bends—there being, of course, a manhole at each place when the direction of the cable alters. The iron pipes which are used for protecting the cables are ordinary cast-iron socket pipes, and three sizes are employed—6in., 4in., and 3in., according to the probable number of mains which will ultimately pass through them. The company do not make it a point to exclude water, for holes are bored in what will be the lower part of each pipe, to allow water which may accumulate to drain off into the soil.

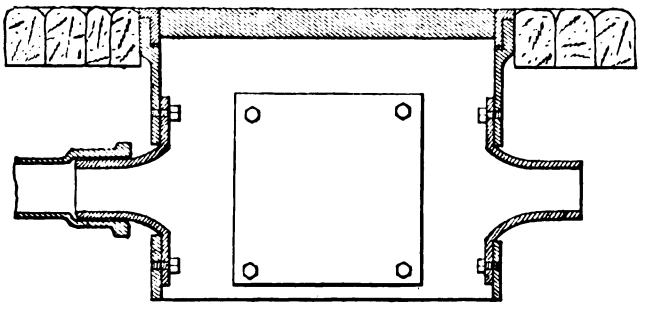

Fig. 13.—House-to-House System. Manhole.

On an average about every 70 yards, but naturally depending a good deal on the distance of the streets apart, there is placed a manhole. The construction of these is much the same as those employed by the General Post Office, and will readily be seen from the drawing (Fig. 13). First of all we have an iron frame about 3ft. long, 1ft. 6in. broad, and 2ft. deep: this has a deep double lip all round the top, while the bottom is open. In each of the four sides there is a large opening with bolt

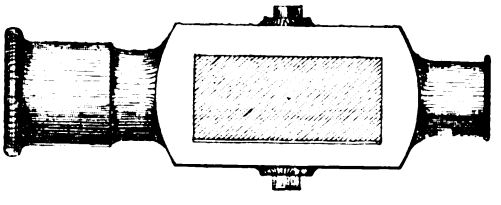

Fig. 14.—House-to-House System. Connecting Piece.

holes round it, to which cone-shaped pieces can be attached from the inside, as shown in the sketch. These cone pieces are made all the same size at the large end, but taper down to a smaller aperture at the other end, and this smaller end is made of three different sizes to fit the sockets of any of the different sized pipes used. These cone pieces are moreover very useful and valuable, as giving a smooth, curved surface when the mains enter and leave the pipes, so that they can be drawn in or out with great facility, and without coming in con-

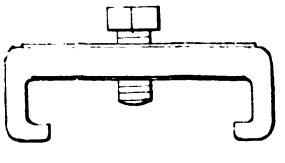

Fig. 15.—House-to-House System. Cast-Iron Clamp used in Connection with the Connecting Piece.

tact with any sharp or angular surface likely to abraid them. If any of these holes in the sides of the manholes are not required to be used, they are covered over with a flat plate placed on the inside. The covers of the manholes are made of a strong iron frame fitting into the deep groove in the top of the manhole frame, and the inside of the frame is filled up with concrete or wood blocks to correspond with the pavement or roadway where the manhole may be situated.

There is a further arrangement for making connections to customers, and in laying pipes this connecting piece is put in opposite every other party wall, so that each house is within quite easy reach of the mains. The exact form of this connecting piece will be best understood from Fig. 14, which almost explains itself. A short piece of pipe is cast with an oblong opening, the opening being about two-thirds of the total length of the pipe. The area of the pipe is somewhat enlarged, for the length of this opening which is finished off square at the top and provided with a flange along each side, while in each side of the box two holes are tapped to take 1½in. wrought-iron gas tubes, these tubes being used for carrying the branch leads into customers' houses. When not in use these holes are filled by screw plugs. A ribbed iron lid with a piece of felt underneath covers the opening in the top of the connecting piece, and it is kept in its place by a cast-iron clamp (Fig. 15) provided with claws at each end, which catch under the lips on each side of the top of the connecting piece. The clamp has a screw in the middle, which can be tightened up as required. Cast iron has been used for this clamp, so that in case of the screw becoming immovable from rust the clamp may be broken by a blow, which could not be done if it were of wrought iron.

London Electric Supply Corporation.

The Siemens concentric cables which this company are laying down, have already been described. It may be further noted that the company have had now for more than two years considerable lengths of indiarubber-covered and braided cable laid in iron pipes, ten cables in each pipe, chiefly under St. James's Park. These cables have stood a pressure of 2,400 volts for the whole time without giving any trouble.

The Ferranti concentric main has already been several times illustrated. It consists of two copper tubes, one inside the other, insulated between by a great number of layers of paper steeped in ozokerit. The outside copper tube is then further insulated and placed in an iron tube. The outer copper and iron tubes are drawn down on the insulation, which makes it very solid. Trial lengths of this tubing have successfully stood enormous voltages. A complete system of joints and junctions has been worked out, and much thought and care has been expended in all the details, which are of a very practical character. As a bold and original attempt to meet the requirements of an underground system of mains applicable to low as well as high pressures, the future working of these mains will naturally excite much interest.

Metropolitan Electric Supply Company.

This company have chiefly adopted a system of indiarubber cables in iron pipes, which up to the present are working extremely well.

St. James's and Pall Mall Electric Lighting Company.

This Company, which works on the low-tension three-wire system, has struck out a set of underground mains for itself of

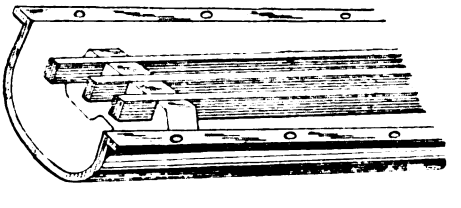

Fig. 16.—St. James's and Pall Mall System. Iron Culvert with Cover removed.

a distinct and original character. A partial description of their mains appeared in connection with an account of the station in a recent issue (*The Electrician*, January 24th), but for the sake of completeness, and because the system is really deserving of careful attention, a fuller account is included here. The type is that of bare copper strips carried on insulators in an iron culvert (Fig. 16). Fig. 17 shows a section of the culvert, which is made of cast iron in lengths of about 3ft. 6in. The lower portion is a trough, about 10in. broad and 6in. deep, with its edges turned over so as to form flanges, one on each side. A correspond-

Digitized by Google

ing and slightly arched cover forms the top of the trough, and is held in its place by a series of nails and bolts, the joints being packed with red lead and yarn. To connect these troughs together when laid, an iron piece of the same shape as the trough and about 5in. broad is fitted on outside, overlapping each trough equally, its flange just coming up under the flanges of the troughs. The joint is then run with lead. The converting piece being a little longer than the outside of the troughs allows a slight vertical or horizontal deviation to be made, so that the culvert can be carried round a moderate curve.

A similar piece of iron covers the joint between two lids, only in this instance a packing of yarn and red lead is used. Brick manholes, cement-lined, are arranged about every 100 feet, into which the culverts come. The manholes are always connected with the nearest drain, and wherever possible the culverts are laid so as to have a slope towards the manholes; where this is not possible the troughing is itself connected with the drains; a syphon box and hydrant is fitted, so that any

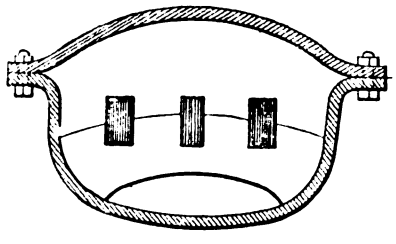

FIG. 17.—St. James's and Pall Mall System. Section of Culvert.

water which may collect can be pumped out, as is done in the case of gas mains. In some cases the manholes too have sumps when drains cannot be got at. The amount of water which collects in the culverts is found to be very little, and to cause no trouble. With the sumps experience soon shows which ones fill up soonest, so that it is easy to arrange for the water which accumulates in them, and which is never much, being pumped out. Across the culvert are placed at intervals of three yards glazed earthenware insulators of the form shown in Fig. 18. These insulators support the conductors, which are formed of bare copper strips, each 2in. wide by ·1in. thick, and it is found practicable to lay mains with a section up to 2 inches in each for the lead and return in the culvert of the size adopted. These strips are obtained in long lengths, and a sufficient number of them are run side by

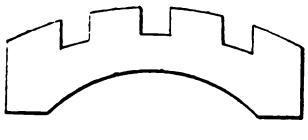

FIG. 18.—St. James's and Pall Mall System. Form of Insulator employed.

side to make up the required section of any feeder or main. When in their places they are flattened as far as possible by hand with a mallet, and held together at frequent intervals by a wire binding a big brass clip of the proper breadth. As already mentioned, the system is a three-wire one, and the ratio has been adopted of one-half for the section of the neutral wire as compared with the positive and negative mains. When the slips are in their places "jockey pieces" of earthenware are slipped across them from above, about every yard, to keep them exactly straight and in position, and then the cover is put on. It will be noticed that the strips employed are broader and thinner than those Mr. Crompton uses.

The mains are broken at each junction box, and connected across by a rigid bridge of less section than the mains, so that in case of accident it would melt before they were injured. By shunting the current this connecting piece can be unclamped and taken off, and the mains disconnected at any time when the current is on. As the system consists of a ring main running right round the district lighted, into which six large feeders convey current at intervals all round, almost any section of the mains or feeders can be cut out without interfering with the rest of the lighting, and repairs and alterations can be made with the minimum of interference with customers.

Connections to customers are made by drilling a hole in the culvert, and screwing into it gas tubing, through which the current is conveyed to the customer by the best class of vulcanised indiarubber cable, which is lapped round and soldered to the mains, the other end terminating at the meter. The Aron meter is used, and all customers are supplied on its indication: it is found to work very satisfactorily.

Current has now been supplied through these mains for 10 months without any stoppage or failure, and although the system has come in for a good deal of criticism, it appears to be thoroughly justifying itself by results. At the same time it is both cheap and easily laid.

(To be concluded.)

REVIEWS.

Medical Electricity and Massage. By H. NEWMAN LAWRENCE, A.I.E.E. (London: George Gill & Sons.)

As Managing Director of the Institute of Medical Electricity, Mr. Newman Lawrence enjoys exceptional opportunities of obtaining practical experience, and of keeping accurate records of the complicated phenomena associated with the application of electricity to the human body. We would therefore express the hope, that this little volume is but a sample of better and more scientific work.

The book "aims at supplying useful data and hints for nurses," for whom it is intended to serve as "a pocket companion." The first few pages are devoted to definitions of the technical terms most commonly used by electricians. The terms selected appear to be taken somewhat at haphazard, but the definitions themselves are concise, and, as far as they go, accurate. We are particularly glad to see that Mr. Lawrence is emphatic as to the importance of accurate "dosage." The absurdity of ordering electricity "by the cell," is a manifest and unfortunately too common an error, but one which we hope Mr. Lawrence's book will help to dissipate. The remaining portions of the work are devoted to electrical data concerning the human body, and are perhaps the more important. Some very interesting tables and charts are given, to illustrate the varying resistances observed in different regions of the body, at different times of the day, and in the same individual; and in this connection Mr. Lawrence justly points out that, in consequence of this varying resistance, widely different doses may be administered on successive days under the same prescription. A series of outline diagrams are added which indicate the motor points of the various parts of the body: they appear to be very similar to those of Eichhorst, but their source is not acknowledged. To each diagram is appended a table enumerating the principal muscles and their action. Possibly in such a work as this, intended as it is for non-medical readers, the actual names of the muscles might have been advantageously omitted, more especially as it is very seldom that a single muscle is alone concerned in any one particular movement, and *vice versâ*. For instance, the *digastricus* is the only muscle credited with the action of opening the jaw, and the *lumbricales* are said "partly to flex and partly to extend the fingers"—a statement which, in the absence of further explanation, may, to say the least, appear to be highly contradictory to the tyro. A very small portion of the work is devoted to massage, but the hints given are useful and accurate, though the same cannot be said of the two final diagrams, in which the anatomy is incorrect and misleading.

On the whole, we think that the author has done his work well, and, considering the small size of the volume, his book contains a large amount of practical information, which those who are in the habit of prescribing and practising electrical treatment will do well to master.

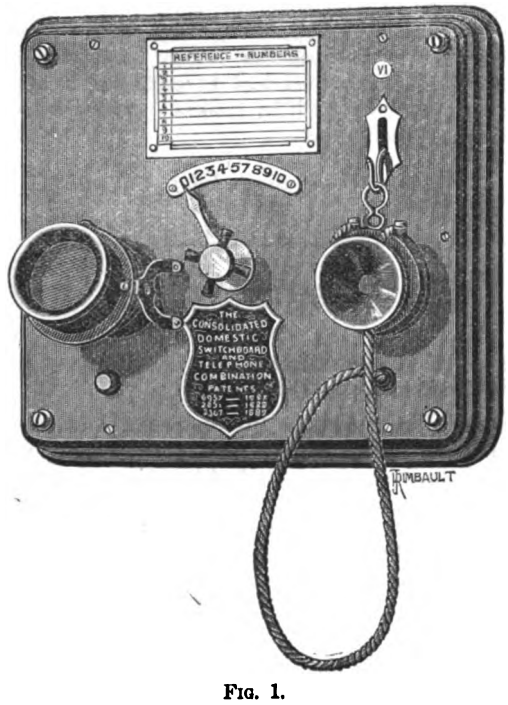
TELEPHONES FOR DOMESTIC USE.

The increasing demand for the telephone in large private houses, offices, warehouses, factories, &c., has led to the construction of several ingenious pieces of apparatus to facilitate the working of the telephone under these new conditions. One of the foremost in effecting improvements in domestic telephony has been the Consolidated Telephone Construction and Maintenance Company, and the following illustration (Fig. 1) shows a combination receiver, transmitter, call-bell, switch-board, and automatic switch, which is now being manufactured by them.



REFERENCE TO NUMBERS
0 1 2 3 4 5 7 8 9 10
THE CONSOLIDATED DOMESTIC SWITCHBOARD AND TELEPHONE COMBINATION
PATENTS
DIMBAULT

Fig. 1.

The patent automatic switch is of great value to the user, inasmuch as it is an utter impossibility for the pointer to remain on a used line. It returns automatically to its normal position after the user has spoken to whatever number he has wished. The working of this switchboard is as follows:—Supposing that a building of 10 rooms or offices have to be connected as a system. One of the combinations would be placed in each room or office. Say that No. 5 requires No. 3—No. 5 places the pointer to No. 3, presses the ringing button under the transmitter, removes the receiver from the switch-hook, and after conversation replaces it. The very act of his doing so causes the pointer to return to 0, and the line is thus cleared. The course of the current will be seen from the diagram (Fig. 2), which illustrates the principle of the entire system. It is from the

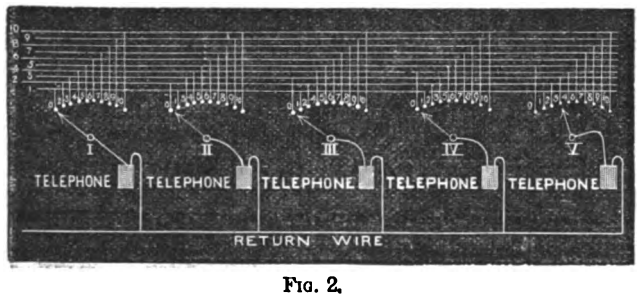


Fig. 2.

instrument at No. 5, through the contact pointer to stud 3, along the No. 3 wire to the 0 stud of No. 3 instrument, thence through the return wire to No. 5 instrument. Fixing, or replacing, or removing the combination is quickly done by reason of each connecting wire having a differently coloured covering. A desk instrument can be provided for a principal, so that communication can be made with all departments without his moving. A cheaper form of combination on this principle with the switchboard separate from the telephone, and non-automatic, is also made by the Consolidated Company.

This switchboard is much the same in principle as that designed by Mr. A. A. Campbell-Swinton, and was described in these columns some two years ago (*Electrician*, January 20, 1888, p. 268). The automatic switch forms, however, a decided improvement.

THE PHYSICAL SOCIETY.

ANNUAL GENERAL MEETING.

At the annual general meeting of this Society held on February 7, 1890, Prof. Reinold, President, in the Chair, the reports of the Council and of the treasurer were read and adopted. The former stated that there had been a very satisfactory increase in the number of members during the year. The number now exceeds 360, of whom 80 are Fellows of the Royal Society. During the year the Council had proposed to change the time of meeting of the Society from Saturday afternoon to Friday evening. The change was adopted by the members by a vote of 129 to 30, and had resulted in a large attendance at the meetings. During the year the second part of Vol. I. of the translations of important foreign memoirs had been issued to members, and it was hoped that the third part would be published early in the present session. The Council had to regret the loss by death of three well-known members—James P. Joule, Warren de la Rue, and Father Perry. A valuable collection of books had been given to the Society by the Royal Astronomical Society. From the treasurer's report it appeared that the balance of the Society had been increased by £120 during the year.

Prof. Hittorf, of Münster, was, at the recommendation of the Council, elected an honorary member of the Society.

The result of the election of officers was declared as follows:—President: Prof. W. E. Ayrton, F.R.S. Vice-Presidents: Dr. E. Atkinson, Walter Baily, M.A.; Shelford Bidwell, F.R.S.; and Prof. S. P. Thompson, D.Sc. Secretaries: Prof. J. Perry, F.R.S., and T. H. Blakesley, M.A., M.I.C.E. Treasurer: Prof. A. W. Rücker, F.R.S. Demonstrator: C. V. Boys, F.R.S. Other Members of Council: W. H. Coffin, Sir John Conroy, Bart., M.A.; Conrad W. Cooke, Major-Gen. Festing, F.R.S.; Prof. J. V. Jones, M.A.; Prof. O. Lodge, D.Sc., F.R.S.; Prof. W. Ramsay, Ph.D., F.R.S.; W. N. Shaw, M.A.; H. Tomlinson, B.A., F.R.S.; and G. M. Whipple, D.Sc. Votes of thanks were then passed—(1) to the Lords of Committee of Council on Education for the use of the room in which the Society has met; (2) To the auditors, Prof. Minchin and Dr. Fison; (3) To the President and Officers of the Society for their services during the year. The meeting was then resolved into an ordinary science meeting. Messrs. E. W. Smith and C. E. Holland, B.A., were elected members of the Society.

The Paper on "Galvanometers," by Prof. W. E. Ayrton, F.R.S., Mr. T. Mather, and Dr. W. E. Sumpner was then resumed.

DISCUSSION.

Prof. AYRTON first made some supplementary remarks on the Paper. Referring to the table given in the abstract which we published last week, he called special attention to the high values of a cubic inch of coil space in galvanometers of the d'Arsonval type, as shown by the last four columns of the table. He then called attention to the table given below referring to three of Elliott's galvanometers:—

No. of Galv.	r	M	D	V	I	DI	$D/r^{\frac{1}{2}}$	$DI/r^{\frac{1}{2}}$	$D/Vr^{\frac{1}{2}}$	$DI/Vr^{\frac{1}{2}}$
1	30,000	34,000	4,000	252	...	...	...	...	...	...
2	3,860	7,550	15,400	250	·01	154	566	5·66	2·26	·023
3	6,000	15,750	32,000	250	·01	320	1,180	11·8	4·72	·027

r = resistance in ohms, M = millimetres deflection when the period is ten seconds and the scale is placed as in the actual use of the instruments. D = deflection in scale divisions per micro-ampere when the period is ten seconds and the scale distance is equal to 2,000 scale divisions. I = moment of inertia of suspended parts in C.-G.-S. units (only approximate). V = volume in cubic centimetres occupied by the convolutions of wire (only approximate).

The instruments 2 and 3 had very light needles with two coils to each, and the suspension was seven inches in length. The values in the case of No. 3 were deduced from Elliott's data obtained by testing with a standard cell which they believed to be a Daniell, but Prof. Ayrton observed that it was quite possible a Grove cell might have been employed, as he believed this was Messrs. Elliott's usual practice. In that case the value of D for this instrument would have to be halved, but even so the result would be very good.

In reply to a question which had been put to him after the last meeting, he stated that, when necessary, the effect of electrification of the ebonite was eliminated by attaching one of the galvanometer terminals to the brass case of the instrument, in which case there would be no charge inside. This, however, was only requisite for measurements of very great delicacy.

With respect to the calibration of ballistic galvanometers, the Professor observed that the methods usually recommended were the employment of an earth inductor or of a condenser charged to a known E.M.F. by means of a standard cell, such as Clark's. The former method he objected to on account of its requiring the determination of the value of the horizontal

Digitized by Google

component of the earth's magnetic force at the place and time of observation, which was difficult and tedious to obtain with accuracy. The second method was open to objection on account of the unreliability of condensers where great accuracy is required. The method which he preferred was that of sending a constant measured current through the galvanometer to be tested.

Mr. BOYS did not agree with the authors of the Paper that the fairest method of comparing galvanometers of different types was under the condition of constant controlling moment, for he considered, as he had already pointed out in his lecture at the Society of Arts, that this gave an undue advantage to instruments of the Gray or Rosenthal type. If the suspended system of four coils in one of these instruments could be reduced in size indefinitely while retaining the period constant, it would ultimately assume the form of a very short magnet within a single coil, and then the deflections would become much greater than before. It was impossible to make very delicate instruments of this kind with silk fibres, as the perpetual shifting of the zero would be indistinguishable from the effects of the current, but if a spider line, or fibre of some other material not subject to this disadvantage—like silk—were employed, instruments of great delicacy and sensitiveness could be obtained. He had succeeded in making most satisfactory instruments of this kind with a needle one-eighth of an inch in length, and having a period as long as 20 seconds; and a group of such needles suspended within a very small coil would be far more sensitive than one of the Gray pattern with its **H** suspension. An instrument of this kind would certainly be more sensitive to external magnetic disturbances than one of the Gray type; but, on the other hand, a much smaller period would be requisite to give the same amount of sensitiveness, so that the magnetic changes taking place during an observation would be much smaller. His own experience led him to the conclusion that the best means of securing very great sensitiveness was to make all the moving parts as small as possible. In the instruments to which he had previously referred, with needles one-eighth of an inch long, the moment of inertia of the suspended portion was about ·0005 C.-G.-S. unit, and yet a period of as long as 20 seconds was obtainable. He thought that winding the inside layers of the coil in the reverse direction to the outer ones was open to the objection that it would make the magnetic field much less uniform, and therefore make it necessary to calibrate the instrument with much greater exactness than would otherwise be required. In making his radio-micrometer, he had supposed, like the authors, that electro-magnets would give the best results; but he found that this was not the case, for unless the amount of copper was double what would otherwise be required, the instrument, owing to the effect of induced currents, became so dead-beat that it would not sensibly move at all when the period exceeded 10 seconds.

Mr. SWINBURNE said that the efficiency of a galvanometer depended on its permanent figure of merit, and it seemed to be necessary to determine this differently for every different use for which the galvanometer was to be constructed. He did not see that there was any great advantage in modifying the construction of a galvanometer in order to obtain proportional readings, as it was easier for instrument makers to construct a scale to fit the galvanometer. He would like to know whether Prof. Ayrton had ever used Lippmann's so-called electrometer: was it not rather a galvanometer? And whether he had found it a sensitive instrument? He pointed out that the instrument alluded to by Prof. Ayrton as the d'Arsonval galvanometer was the same in principle as the recording arrangement employed by Sir William Thomson in the siphon recorder, and stated that it was originally patented, but without any mention of a mirror, by Varley. He thought the modification adopted by the authors of weakening the spring and replacing its action by means of a directing magnet was merely replacing one fault by another; and the spring was the more permanent arrangement. He had always thought that the method of calibrating ballistic galvanometers by means of a constant current was the one in ordinary practical use. At any rate it was employed by Hopkinson in his experiments on the curves of magnetisation of iron. Mr. Boys' argument about the Gray type of galvanometer appeared to involve the assumption that the size of a magnetic needle could be diminished indefinitely without diminishing the strength of the poles.

Prof. FITZGERALD observed that Lord Rayleigh had shown in a Paper read before the British Association that it followed from optical principles that the observation of the edge of the mirror by means of a sufficiently powerful reading microscope would be just as advantageous as the employment of a spot of light, however far the mirror was removed from the spot. A much greater advantage could therefore be obtained if a long pointer were attached to the edge of the mirror, and its position read by means of a microscope. The practical difficulty in the use of this method, however, was that it was impossible to distinguish between side-way motions of the mirror and its rotation, unless both ends were observed simultaneously, and he had made some attempts to devise a suitable arrangement for doing this. This difficulty did not arise when a spot of light was employed.

Prof. AYRTON in replying stated that he had never employed coils so small as those described by Mr. Boys, and with those he had used he had never found the damping to be too great; indeed, they had wound the coils upon thin strips of copper in order to increase the damping. They had moreover employed a stronger magnet than had ever before been used for the purpose in England for their most sensitive instrument. The exciting current of the electro-magnet was kept constant by including in the circuit an ammeter, the pointer of which moved right across the scale for a change of 0·1 per cent. in the strength of the current on either side of the desired value. He did not agree with Mr. Swinburne that proportionality of reading was a matter of indifference, as it was extremely difficult to construct a three-foot scale to follow all the vagaries of an instrument of the original d'Arsonval type. He was quite aware that M. d'Arsonval was not the first inventor of the type of instrument known by his name, but he had continued to call it by the name by which it was generally known, as M. d'Arsonval was the first to practically employ the principle in the construction of galvanometers. He had employed the so-called Lippmann electrometer, which was really a galvanometer, as it allowed an appreciable current to pass. It was in fact an extremely delicate voltmeter. He had thought the constant current method of calibrating galvanometers worthy of mention, because it was not described in any of the text books, even the most recent ones.

MEETINGS OF SCIENTIFIC SOCIETIES, &c.

(To night) FRIDAY, February 14th.

ROYAL INSTITUTION.

9 p.m. Lecture: "Problems in the Physics of an Electric Lamp." By Prof. J. A. FLEMING, D.Sc.

SATURDAY, February 15th.

ROYAL INSTITUTION.

3 p.m. Lecture: "Electricity and Magnetism." By the Right Hon. Lord RAYLEIGH, F.R.S.

MONDAY, February 17th.

LONDON INSTITUTION.

5 p.m. Lecture: "The Poetry of William Dunbar." By Prof. W. P. KER, M.A.

SOCIETY OF ARTS.

8 p.m. CANTOR LECTURE III. 1: "Stereotyping." By THOMAS BOLAS, F.C.S.

TUESDAY, February 18th.

ROYAL INSTITUTION.

3 p.m. Lecture, "The Post-Darwinian Period." By G. J. ROMANES, F.R.S.

SOCIETY OF ARTS.

5 p.m. Foreign and Colonial Section. Paper to be read, "Ocean Penny Postage and Cheap Telegraph Communication between England and all parts of the Empire and America." By J. HENNIKER HEATON, M.P.

INSTITUTION OF CIVIL ENGINEERS.

Ordinary Meeting. Papers to be read: "The Shanghai Water-Works." By J. W. HART, M.Inst.C.E. "The Tytam Water-Works, Hong Kong." By JAS. ORANGE, Assoc.M.Inst.C.E. "The Construction of the Yokohama Water-Works." By J. H. T. TURNER, Assoc.M.Inst.C.E.

ROYAL VICTORIA HALL.

8:30 p.m. Lecture, "Eyesight and Some of its Defects." By Dr. COLLINS.

WEDNESDAY, February 19th.

CIVIL AND MECHANICAL ENGINEERS' SOCIETY.

7 p.m. Ordinary Meeting. Paper to be read, "Italian Water Supply." By A. FAIRLIE BRUCE.

ROYAL METEOROLOGICAL SOCIETY.

7 p.m. Ordinary Meeting. Papers to be read:—"Observations on the Motion of Dust, as Illustrative of the Circulation of the Atmosphere, and of the Development of Certain Cloud Forms." By the Hon. RALPH ABERCROMBY, F.R.Met.Soc. "Cloud Nomenclature." By Captain D. WILSON-BARKER, F.R.Met.Soc. "An Optical Feature of the Lightning Flash." By ERIC S. BRUCE, F.R.Met.Soc.

SOCIETY OF ARTS.

8 p.m. Ordinary Meeting. Paper to be read: "The Organisation of Secondary and Technical Education in London." By Prof. SILVANUS P. THOMPSON, D.Sc.

THURSDAY, February 20th.

ROYAL INSTITUTION.

3 p.m. Lecture: "The Three Stages of Shakespeare's Art." By the Rev. Canon AINGER, M.A.

LONDON INSTITUTION.

7 p.m. Lecture: "Franz Schubert and his Successors." By CARL ARMBRUSTER.

INSTITUTION OF ELECTRICAL ENGINEERS.

8 p.m. Ordinary Meeting.

CHEMICAL SOCIETY

8 p.m. Papers to be read: "The Behaviour of the More Stable Oxides at High Temperatures." By G. H. BAILEY, D.Sc., and W. B. HOPKINS. "The Influence of different Oxides on the Decomposition of Potassium Chlorate." By G. J. FOWLER, M.Sc., and J. GRANT.

***** Particulars of meetings to be held or Papers to be read before Scientific Societies during the ensuing week should reach us not later than Thursday, 6 p.m.**

The Electrician.

Published every Friday. Price Fourpence; Post Free, Fourpence Halfpenny
Editorial, Publishing and Printing Offices:

No. 1, SALISBURY COURT, FLEET STREET, LONDON, E.C.

Telephone No. 2714. Telegrams: "ELECTRICIAN NEWSPAPER, LONDON."

All Communications to be addressed to "THE ELECTRICIAN," *1, Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to* "THE ELECTRICIAN."

All letters intended for insertion in "THE ELECTRICIAN," *or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

"THE ELECTRICIAN" *is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.*

"THE ELECTRICIAN" *is on sale at the railway bookstalls throughout the United Kingdom on Friday morning, and can be obtained of all Booksellers and Newsvendors; or direct from the Publishing Offices as above*

SPECIAL NOTICE.

Owing to the increase in the number of pages of "THE ELECTRICIAN," in order to partly cover the increased postage, we have been compelled to revise the rates for Foreign Subscriptions, which are now as follows:—

	3 months.	6 months.	12 months
For Foreign Parts and Colonies:—	s. d.	s. d.	s. d.
Within Postal Union	6 6	12 6	24 0
Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7 6	14 6	28 0
The rates for the United Kingdom remain as follows:—	5 0	10 0	19 6

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to the office.

TRADE ADVERTISEMENTS *intended for the current issue must be handed in not later than First Post on Thursday morning.*

SMALL PREPAID ADVERTISEMENTS *(for Rates see page xiii.) are accepted up to 4:30 p.m. on Thursday.*

TECHNICAL PRINTING.

"THE ELECTRICIAN" PRINTING AND PUBLISHING COMPANY (LIMITED) *beg to inform Electricians, Electric Light Engineers, &c., that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

"THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK.

Royal 8vo, 5s., postage extra.

Early in each year is issued "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1889 Edition consisted of more than 600 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with popularly-written Biographical Notices of the leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

The issue for 1890, which is still further enlarged and improved (making 850 pages), is NOW READY. Orders should be forwarded at once to the Publishing Offices, Salisbury-court, Fleet-street, London, E.C.

TELEGRAPH AND TELEPHONE.

The figures relating to the development of English telephonic business published in our annual summary for the year 1889 are sufficiently remarkable in themselves to deserve the careful study of those ingenious persons who take note of the statistics of novel and prosperous industries. But besides this they possess a significance for a far wider circle of students, and, indeed, for all classes of business or professional men who watch with anxiety the relations which continue to subsist between the telephone companies and the State telegraphs of this country. Those relations can hardly be said to be friendly: on both sides action has been taken which portends overt hostility at no distant date; and on neither side has there been overtures of a kind at all likely to lead to that co-operation which is so much desired by the public, and so necessary to the permanent welfare of the parties chiefly concerned. To every practical telegraphist it was evident from the moment of its discovery, that the telephone would sooner or later become either an adjunct or a rival to the telegraph itself; and when in this country the legal decision was pronounced that telephony was only a variant form of telegraphy, the absorption of the lesser by the greater was reduced to a mere question of opportunity or expediency. Its expediency has long been admitted; but the opportune moment has not yet arrived, though some people think it is not far off. Meanwhile the two systems work apart, the State having no telephony of its own

Digitized by Google

worth speaking of, and admitting no connection with telephony outside; while, on the other hand, the telephone companies have not only obtained a vast amount of business for telephony proper, but have developed it over widely separated areas, so that it is hardly distinguishable from the telegraphs, supposed to be exclusively worked by the State.

It it needless to go over once again the oft-told story of this unfortunate complication. Suffice it to say the representatives of the State telegraphs for the time being have swayed from side to side in their policy with regard to the companies, and until the last year or two have adopted no firm or consistent attitude towards them. Taking advantage of this vacillation the companies have pursued their course, as they were entitled to do, with a strict regard to commercial considerations, and latterly, no doubt with an eye to making the best bargain possible if the POSTMASTER-GENERAL should carry out his half-revealed intention of repeating upon them the *coup* which he successfully delivered last year at the now defunct Submarine Telegraph Company. Whether the telephone companies have acted wisely in their later developments is a question which the general public regard with perfect indifference. One thing, however, may be said as touching the outlook from a shareholder's point of view, namely, that long-distance telephony, as it is called, will test the financial soundness of the directors' calculations to the utmost; for splendid as it may look on paper, it has never yet been made to pay except in conjunction with long-distance telegraphy. American statements on the subject are altogether untrustworthy, and in any case are wholly inapplicable to our own country. France provides a safer illustration; and in France the State has rudely got out of the growing entanglement by absorbing the telephone companies' business on terms which nothing but compulsion would have rendered acceptable.

Most probably this example will be speedily followed elsewhere on the Continent; and in one form or other by the British Post Office on the very first opportunity, unless political exigencies should intervene to prevent it. And this not so much because the telephone is a competitor of the telegraph, as because the proper and legitimate functions of the State telegraphs are being gradually diverted into private hands. In other words, telephony being a mode of telegraphy, the public which bought the exclusive right to the latter have a right to exclusive control over the former. If the telephone had remained, as some people supposed it would, a sort of speaking tube from one house to another, no occasion would have arisen to take its management away from private speculation. But, much to their surprise, it has grown to be a speaking telegraph, yet with none of the advantages as regards cost and organisation which a State telegraph is bound to confer on the community. The telephone, in its present stage of development, ought, therefore, now to come under the control of the administration of that public department which has managed the telegraph so admirably that it is at once the cheapest and swiftest means of communication known in the whole world.

That the telephone, as at present administered by private hands is neither as cheap nor as swift as it might be under State control is notorious. And that the telephone companies' business has so remarkably developed under such adverse conditions is only another indication of what it might become if the two systems of telephony and telegraphy were combined under one administration. Some interesting particulars bearing on this point have lately been published in these columns from our Scandinavian correspondent, whose letters have furnished a striking illustration of what has been done with telephone and telegraph combined in the hands of the Swedish Government, and information which we have received from a valued Danish correspondent tells the same story with respect to Denmark. In both Sweden and Denmark the telephone lines controlled by the State are patronised almost as much as the telegraph, and the two systems, instead of impeding each other's development, unite to minister to the wants of the public. For the present private competition is not forbidden in Sweden, but is conducted under strict regulations, and the State telephone lines are pushed forward notwithstanding, with the result that the systems are worked at their very best, and at prices which make ours look exorbitantly high. According to our correspondent's letter, published in *The Electrician* of January 10th, the Swedish Government has authorised a sum of £8,000 to be expended annually on telephone extension; and, as an example of the manner in which it is being made to serve commercial purposes, mention is made of steamers while in port being connected by wire with their respective houses of business in the towns. No doubt a similar enterprising spirit would actuate the English State Telegraph Administration in respect to the telephone if considerations of fair play to the companies, from whom royalties are exacted, did not stand in the way; but as regards the companies, so long as they are free to do what they please, they will of course make the most of their opportunities, imposing the highest possible charges that the public can be induced to pay. Nobody can blame them for this, and the present Government is, perhaps, equally blameless in the matter. But this condition of affairs is extremely inconvenient to the public, and the sooner it is put an end to the better it will be for them, for the Government, and for the companies alike.

THE INSTITUTION OF ELECTRICAL ENGINEERS.

THE THEORY OF ARMATURE REACTIONS IN DYNAMOS AND MOTORS.

BY JAMES SWINBURNE.

It seems to be generally supposed that electrical engineers are in full possession of means for calculating out and designing a dynamo or motor. This is no doubt the case as regards very small machines, and as regards large machines when considered with reference to no load. The effect of the armature current is mentioned in the classical Paper of Drs. J. and E. Hopkinson, the excitation necessary at full load being given in terms of the armature current turns and the lead of the brushes; but as the lead of the brushes is determined after the machine is made, that Paper gives the first step towards a solution of the armature reaction, but does not go farther. As not only the excitation necessary at full load, but also the best dimensions of the magnets and the proper shape of the pole-pieces, depend on the armature reactions, and as the armature reactions are of immense importance in large machines, such machines cannot be designed with accuracy unless the armature reactions and position of the brushes at full load can be foretold. The armature reactions are often regarded as obscure and unimportant phenomena, but, except in very small dynamos, the error due to neglecting them would be much greater than that due to neglecting the waste field, which has, of late, received so much more attention.

As most engineers are now in the habit of using C.G.S. measure, the C.G.S. system will be used in this Paper. The only new importation into dynamo work will be the idea of magnetic potential, as it is exceedingly convenient for explanation. The magnetic potential is, of course, the line integral of the magnetic force, and is 4π times the current-turns. As it is cyclic, we must take the line integral once round a circuit interlinked with the exciting circuit. Any point of the circuit may be assumed as of zero magnetic potential, but generally difference of potential is alone considered. The magnetic potential may be thought of as ampere-turns, or might be measured in ampere-turns; but as such a method is unusual, it will be taken in C.G.S. measure, being denoted by the symbol Ω; and for want of a unit of its own, it may be measured in ergs. An ampere-turn thus gives a magnetic potential of $4\pi/10$ ergs, or 1·26 ergs.

Digitized by Google

Magnets and Winding.

As single-magnet machines are very largely used now, and a type can be taken which is approximately that used by most of the large representative makers, such a machine may be taken as an example. A formula which gives the size of iron, and the excitation needed, will then be worked out.

The vertical line through the centre may be taken as at zero magnetic potential at no load. Assuming the length of the core to be the same as that of the pole-pieces, and calling the external radius of the core r, and the radial depth of the discs b, and the length of core a, and the armature induction B_a, the surface integral of the induction, or what may be for shortness called the total armature induction, is $2\,a\,b\,B_a$. The desired armature induction is here assumed. In practice different makers prefer different inductions, and to discuss the various considerations would take too much room, and would be outside the subject of this paper. The distance, l_a, which represents the length of iron that has to be magnetised to the induction B_a depends on the arc of embrace of the pole-pieces; but a large error in the estimate of this length causes a very small error in the design of the machine, as very little of the excitation is spent on this part of the magnetic circuit. The fall of magnetic potential over $\frac{1}{2} l_a$ is $\frac{1}{2} l_a B_a/\mu$, and may be written $\frac{1}{2} \Omega_a$. The induction in the air gap depends on the armature induction, the radial depth of the discs, and the pole-face angle. It will be written B_g. The line integral of the induction across the gap is $\frac{1}{2} g B_g$, where g is the distance across the gaps. $\frac{1}{2} g B_g$ may be written $\frac{1}{2} \Omega_g$. The fall of potential from the middle of the yoke to the pole-piece depends on the length of the circuit and the induction. It may be written $\frac{1}{2} l_m B_m/\mu$, or $\frac{1}{2} \Omega_m$. The induction that can best be used in the field magnets depends,

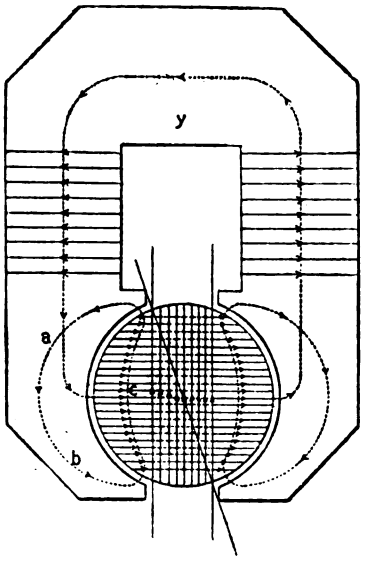

Fig. 1.

again, on many things that cannot be discussed shortly. As it is generally best to use a lower induction in the yoke, that must, of course, be taken into account. As the other half of the magnetic circuit is similar at no load, the line integral of the magnetic force needed in the shunt is $\Omega_s = \Omega_a + \Omega_g + \Omega_m$. As to the length of the field magnets, it depends on the total excitation needed. Different makers allow different lengths per thousand ampere-turns on the fields.

At full load the armature induction has to be increased to allow for the resistance of the armature and series coils, and sometimes for the leads also. A higher value is therefore taken for B_a, and therefore for Ω_a. The effect of the armature current itself may be divided into two components; and in the case of a drum armature, which may be taken for the sake of simplicity, the electrical effect is the same as if the external conductors were connected across the ends as shown in Fig. 1. There is thus a belt of current-turns opposing the field excitation, and another belt acting at right angles to it. These may be called the back and the cross ampere-turns, and the induction produced by them, the back and the cross induction respectively. The breadth of these belts, or the number of turns in each, depends on the lead of the brushes. For the present the lead of the brushes may be assumed. The extra difference of magnetic potential between the pole-pieces due to the back current-turns is $\pi\, C\, n_b/10$, where C is the armature current in amperes, and n_b the number of external armature conductors in the belt of back turns, n_a being the number of external armature conductors. This may be written,

$$\Omega_b = \pi\, C n_b/10 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

The difference of potential of the pole-pieces at full load is thus $\Omega_a + \Omega_b + \Omega_g$; and Ω_a and Ω_g are greater than at no load, because the armature and gap induction are higher. The difference of potential between the pole-pieces may be shortly written, Ω_p. In a given type of dynamo the percentage of waste field varies directly as the difference of potential of the pole-pieces, provided the field-magnets are not strongly magnetised, and is independent of the linear dimensions. The actual waste field, however, varies directly as the difference of magnetic potential between the pole-pieces, and directly as the linear dimensions, or as the diameter of the armature. If the armature cross-sectional area is $2\,a\,b$, and the armature induction is B_a, and if the field induction desired is B_m, the cross-section of the field-magnets must be

$$A_m = 2a\,b\,\frac{B_a}{B_m} + \frac{r\,\Omega_p}{M\,B_m} \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where M is a coefficient depending on the type of the machine. This coefficient can be readily determined from another machine of the same type but of different size, and an error in its estimation makes comparatively little difference in the dynamo.

In ordinary single-magnet machines M is generally about ·08 to ·085; in double-magnet machines it is less. Of course a great deal depends on the mounting of the dynamo. A machine let into a bed-plate, as is often necessary in the case of direct-coupled engines, has more leakage.

An equation for the shunt and series excitation is now to be found. From (1) the field induction is found—

$$B^m = \frac{2\,a\,b\,B_a}{A_m} + \frac{r\,\Omega_p}{MA_m} \quad . \quad . \quad . \quad . \quad (3)$$

Giving the value of B_a and Ω_p at no load, the value of B_m at no load is obtained. The shunt excitation is thus

$$\Omega_s = l_a B_a/\mu + g B_g + l_m B_m/\mu_m \quad . \quad . \quad . \quad . \quad . \quad (4)$$

in ergs, or this number divided by 1·26 in ampere-turns. By giving the full-load values of B_a and Ω_p the total excitation,

$$\Omega_s + {}_m = l_a B_a/\mu_a + \pi\, C\, n_b/10 + g B_g + l_m B_m/\mu \quad . \quad . \quad (5)$$

is obtained, and, of course, the difference gives the series excitation. Of course the full-load field induction has already been assumed in finding the size of the magnets.

It must not be forgotten that all this time it has been assumed that the lead of the brushes, and therefore Ω_b, is known.

Returning to Fig. 1, a closed line, $a\,b\,c$, may be drawn which is interlinked with all the armature conductors under the pole-piece. The magnetic potential round this circuit is

$$\Omega_c = \theta\, n\, C/10 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

when n is the number of armature conductors, and C is the armature current as before, and θ is the angle of embrace of the pole-piece. As the permeability of the iron, both in the part of the armature and of the pole-piece through which this line passes, is great, the whole difference of potential may be taken as being between the core and pole-piece. The induction under the leading corner, due to cross current-turns only, is then $-\frac{n\,C\,\theta}{2g \times 10}$, and under the trailing corner it is $+\frac{n\,C\,\theta}{2g \times 10}$. The field is thus weakened under one corner, and, provided the permeability of the iron is practically infinite, equally strengthened under the other, being at its normal value half-way down. The cross induction has in this case no direct effect in increasing or lessening the E.M.F. of the machine. If a dynamo were enlarged to scale, the field excitation would increase as the linear dimensions, but the armature current-turns, assuming the same current-density, would increase as the square of the linear dimensions. If the electromotive force of the machine were kept the same, they would increase faster, as the insulation would take proportionally less room. It is thus evident that a size would soon be reached when the cross induction under the leading corner would be equal to the normal induction due to the field excitation, and there would be no field to reverse the current in the section being commutated. The size at which this takes place varies according to the practice of makers, and is generally above the size in common use, as the output of a given armature is generally much smaller than might be taken from it. Machines with single magnets, and fairly large outputs for the size of their armatures, become difficult to design when they have armature above 35 to 40 cm. diameter. The fault can to some extent be corrected in single-magnet machines by making the polar angle —that is, the area of the pole-face—small. There are then fewer cross current-turns, and the induction in the gap is greater, so there is less chance of reversal of induction under the leading corners. This demands more field excitation and larger field magnets, as the difference of magnetic potential between the poles is greater, and so the waste field is greater. If the pole-pieces are made small, so as just to carry the induction due to the field coils without saturation, one side will be to some extent saturated by the addi-

Digitized by Google

tional induction due to the cross current-turns. In Fig. 2 the pole-piece is small across $a-b$, and the iron may need some magnetic force there, so the whole of the magnetic force of the cross-current turns will not be spent on the gaps, and the cross induction will thus be less. On the other side, of course, the cross induction is not lessened, as the iron is less magnetised. The resulting field will not be symmetrical. If the armature is Gramme-wound the lower brush will need more lead than the upper. Sparking at the lower brush in single-magnet Gramme machines has been frequently noticed by dynamo makers. Of course, it may be partly due to the poles being too small in section, so as to throttle the main induction of the field-magnets, but it is much more often

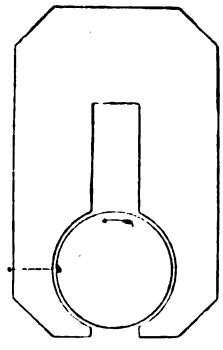

Fig. 2.

caused by the cross induction. If the armature is drum-wound, throttling the cross induction on one side will do some good in lessening the cross induction; but it is difficult to throttle the cross induction without also throttling the field induction proper, and wasting field exciting power.

Fig. 2 may be taken as a diagram of a 30cm. or 12in. armature machine of about the usual type, with the magnets rather close.

If there were no cross induction the pole-pieces would not be strongly magnetised anywhere, but when the cross induction is superimposed, the neck reaches a high magnetisation, the in-

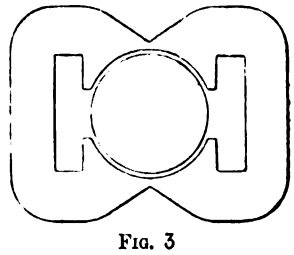

Fig. 3

duction in this case amounting to about B=15,800 there, and to about B=17,200 a little higher up. If it were not that the cross induction is lessened by the saturation of the iron, the neck would rise to B=17,500, and in the region 5cm. or so above the centre line to B=18,600. The difference of magnetic potential between a point a little below the middle and the top of the pole-piece comes to about 1,880 ergs. The effect of this is that more than 1,000 extra ampere-turns are required on the field-magnets. In a Gramme machine the effect is very easily observed by the use of a pilot brush. A resistance of, say, 100

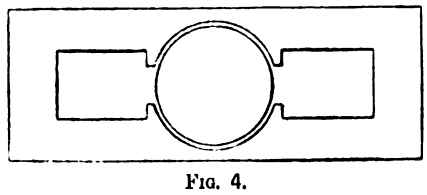

Fig. 4.

ohms is connected between the terminals of the machine. The pilot brush is connected to one terminal of a detector, and the other terminal is connected successively to points in the resistance corresponding, say, to 95, 90, 85 ohms, and so on. The positions of the brush for the zero readings are noted. This avoids errors due to slight variations of speed, which give trouble in the first instance, and errors due to bad contacts. With a drum this method does not give the distribution of the field, as each convolution is on both sides of the armature; but if one pole-piece is highly magnetised by the cross induction, the half of the armature under the upper left and lower right-hand halves of the pole-pieces (in Fig. 2) gives a lower electromotive force than the other. This effect is sometimes very marked in machines with cast-iron pole-pieces.

A double magnet two-pole machine can be made up to a larger size than a single by shaping the pole-pieces so as to throttle the cross induction. Two common types of machine are shown in Figs. 3 and 4 with the pole-pieces so cut. If it be assumed for the moment that the armature-section current can be reversed with no appreciable field, the largest pole-angle that can be used is when the gap induction due to the field excitation is equal and opposite to the cross induction under the leading corner—that is, when

$$\theta = 2\sqrt{\frac{b\,y\,B_a \times 10}{n\,C\,(r+\frac{1}{4}y)}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

As the armature sections need a sensible field to reverse them, the pole angle must be less than this.

(To be continued.)

THE USE OF ELECTRICITY IN MINES.*

BY M. CHALON, C.E.

The applications of electricity to underground work are becoming so numerous that it is possible to predict that in the near future the electric current will be used nearly everywhere in place of mechanical power. Even in coal mines, which are now so admirably equipped with mechanical appliances on account of the economy necessary in order to sell their output, steam, compressed air and water under pressure are being slowly replaced by the electric current. It may be employed for lighting at the bottom of the mine, and at the same time for a similar purpose on the surface, and for the communication by signals, and for the telephone. It will furnish at any depth, at different levels, and at various distances, the motive force for underground haulage, by cable or inclined planes; for the removal of material thrown by blasting; for pumping water; for ventilation; for drilling; for coal cutters, and, indeed, for running motors and machines of all kinds. All these many applications require only a dynamo engine and conducting wires.

It is in metalliferous mines that the application of electricity is becoming most valuable. Such mines usually possess many disadvantageous conditions for working, because they are almost always situated in districts that are not easily accessible, where fuel is expensive, and where transportation is an almost insurmountable difficulty. In such cases there is usually in the vicinity some waterfall, a swift river, or even a simple stream, whence the natural power may be transformed by the aid of a turbine and a dynamo, into currents of electricity which may be used for lighting, for the breaking and transportation of the ore, and even for the treatment of the ore at the mine by electrolysis or heat. In some cases, it is possible to sink an artesian well to produce an artificial waterfall by means of a reservoir more or less elevated. Indeed, it is possible to predict that the time is not far distant when it will be possible to work all mines with profit, especially those which from their inaccessibility have been thue far allowed to remain unproductive.

The Firing of Blasts by Electricity.—The use of the electric current for igniting charges of powder is perhaps the oldest application of electricity in mines. It is much more economical to fire charges by means of electricity than by the use of fuses, as is shown by the following tables in the case of sinking a shaft of 500 metres:—

	Francs.
Expenses of material and of a magneto machine for four simultaneous blasts, in sets of either 6, 8, or 9	80
Five hundred metres of double conductor, consisting of two wires covered with gutta-percha and cotton, and wrapped together with cotton thread, at the rate of 16 francs for 100 metres	80
Putting in place and sundries	25
Total	185

The operator requires no aid, for if the wires break, or are worn by rubbing, they can be easily repaired; hence they should last for years. Nevertheless, their cost price should be saved in a single year. In a large mine it is not too much to calculate an average of 4,000 to 5,000 blasts each year, and with this apparatus it would be equivalent to 4 centimes for each firing.

The cost of firing is (*a*) when powder is used—

	Centimes.
A simple primer for a spark with 1 metre of double conducting wire	10
An iron coupling wire covered with cotton, costing 3fr. a kilogram, with a length of 1½ metres, of which the price would be 7½ centimes. The loss from a series of explosions would not exceed 5 per cent.	0·37
Total	10·37

* Abstract of Paper read before the Mining and Metallurgical Congress, Paris, September, 1889.

Digitized by Google

(*b*) When dynamite is used—

A primer with a detonator containing 0·75 grammes of fulminate and a double conductor of 1 metre	15·
A coupling wire, with loss of 5 per cent. as before	·37
Total	15·37

The double conductor of the primer may be collected after the explosion, and may be used again as a coupling wire, or for other purposes. Its value may be estimated at 1 centime.

The running expenses after taking off this amount are :—

	Centimes.
(*a*) Using powder	9·37
(*b*) Using dynamite	14·37

Total cost as follows :—

	a. Centimes.	*b.* Centimes.
Material and plant	2·00 ...	2·00
Running and expenses	9·37 ...	14·37
Total	11·37 ...	16·37

Comparing these figures with those corresponding to the use of fuses, we find that with powder the cost is with ordinary fuse 6·5 centimes, and with gutta-percha fuse 25 centimes. With dynamite and ordinary fuse it is 12 centimes, and with gutta-percha fuse 29·5 centimes. The use of the ordinary fuse would appear at first sight to be the most economical, but it must be remembered that this fuse is but little used, even in dry work, because it is more easily injured and its manufacture is less careful. Besides, it is frequently doubled, in order to obviate the chances of failure. But the comparison between the prices obtained from the ignition by the use of a gutta-percha fuse or by electricity is altogether in favour of electric fuses. If, in addition to the fact of its economy, that by the latter process perfect security from danger is obtained, a much greater advantage is gained, and, finally, a better utilisation of the explosive material is secured in consequence of the simultaneous explosions; hence it can be safely accepted that the use of electricity is necessary, and soon will be used for all working in mines, espe cially in the excavation of shafts.

Lighting.—Electric lighting in mines consists of two kinds:—First, permanent lighting by stationary lamps, and second, lighting by portable lamps. In the first case arc lamps are used for all work on the surface, while incandescent lamps are employed for underground work. It is underground that the advantages of electricity are particularly appreciable. The work becomes more sure, more regular, more rapid—and, a circumstance which seems strange to relate, it appears that the moral nature of the miner improves with the environment of an agreeable light. Permanent lighting is not applicable to the working faces. The use of portable lamps attached to the principal conductors, as was tried at first, is dangerous, and, above all, inconvenient. The coming in contact produces a spark, and besides, the moving of the switch-board offers considerable difficulty, as a false movement may crack the glass, break the cable, or expose the insulation. It is, therefore, necessary in the drifts and working faces to make use of a lamp that is independent of all conducting wires, easily transported, capable of being suspended from the roof, attached to the walls, placed on the ground, or, in a word, a lamp that can be moved in all directions without losing its luminous intensity. To the same degree that the problem of permanent light is simple and easy to solve, so is that of portable lamps complicated and difficult. The following are the requisites for a good electric lamp for miners:—It should first be of simple construction and solid; second, as light as possible; third, easy to take care of and recharge; fourth, furnish a light having an intensity nearly constant for eight hours; fifth, have a lighting power of 1 to 1½ candle-power as a minimum; and sixth, be inexpensive. In making comparison, we use as standard the Davy safety lamp (Clanny, Marsaut, Mueseler, Fumat, &c.), and it will be recollected that they are simple and solid, that the weight does not exceed 1 to 1½ kilograms, that they yield a constant light of from ⅛ to ½ candle for 10 hours, at an average expense of 15 centimes for each filling. One of the first portable electric lamps was that made by M. Trouvé, in which the generator of electricity is a bichromite battery, but the incandescence is only produced when the lamp is carried in the hand or suspended by a hook. Unfortunately the Trouvé lamp is heavy, its light is not steady, and it does not last longer than two hours. Numerous models of lamps, with primary and secondary batteries, were submitted to the English Commission on Accidents in Mines (1879-1886), but none received approbation. Since 1886, however, considerable progress has been made, and good accounts have been received of several lamps that are used in English mines, such as the Schanschieff and the Friedlander lamps, with primary batteries, and the Swan, Pitkin, and Higson lamps, using storage batteries. Swan has constructed an indicator which he adds to his portable electric lamp. He takes advantage for this purpose of the well-known property that a red-hot platinum wire has of becoming more brilliant in a fire-damp atmosphere than in pure air. It is difficult to say which variety of portable lamp is the best. It is certain that in mines where there is already a good electric plant a lamp with a secondary battery may be used with advantage, but in all other cases a primary lamp is preferable. It is true, however, and must be said, that as yet no lamp with a primary battery exists that is really practical and adapted to the exigencies of portable lighting in mines. The lamps actually in existence are far from fulfilling all of these desiderata. Some are too expensive, too heavy, too cumbersome, or have too great a resistance, while others contain corrosive liquids or are subject to electrical leakage.

Signals.—In mines where an electric current is in use all of the working places in the mine and the surface are connected by bells or a telephone system. The code of signals is generally very simple, and consists only of one, two, or three bells. By means of signals and the telephone, a permanent and instantaneous communication is established between the bottom of the mine and the surface. The mine ceases to be isolated, and it may be said that all its movements, all its pulsations, are registered above ground. In case of accident, aid may be called for and sent to the exact locality at once. The combination of signals, and the electric light in the workings, makes possible a greater rapidity in the method of mining.

Machine Drills.—The operation of drilling by percussion with electricity offers great difficulty, but, nevertheless, some interesting experiments have been made in the United States by the Sprague Electric Motor Company, the Union Electric Company, and various engineers. In all the experiments the bit is connected by a crank to the armature of an electric motor, in which every revolution corresponds to a blow struck by the tool. The application of an electric motor to rotary drilling, such as a steel cutter or diamonds, is much easier, for the motion of the armature may be communicated directly to the gearing that controls the tool holder. Taverdon has made some attempts in this direction with his diamond crown drill. Tedesco has also sought to apply the use of electricity to his drills.

Mechanical Cutting.—The electric cutting machine of Messrs. Bowes, Blackburn, and Mori has been recently (1887) tested in England. The part carrying the tool-holder, which consists essentially of a plate provided with blades or knives in the form of a star, receives its force from an electric motor located in the same frame and having a force of 6 to 9 horse-power. This motor is connected by flexible conductors to a dynamo. The cutting wheel describes a quarter of a circle in the coal mass, which it cuts away to the depth of about a metre. The carriage is attached to a wheel and axle, by means of which it can be moved along the face. It is possible to dispense with attaching the motor to the carriage, but then it is necessary to move it by chains, or by means of a rope and pulley. The Lechner cutting machine tested in the coal mines of Pennsylvania is attached to an electric motor transmitting power by means of a cord. A single motor will do the work of three cutting machines operating successively, thus permitting continuous working, for while the second or third cutting machine is in operation, the coal cut by the first can be loaded.

THE ABDANK-ABAKANOWICZ ARC LAMP.*

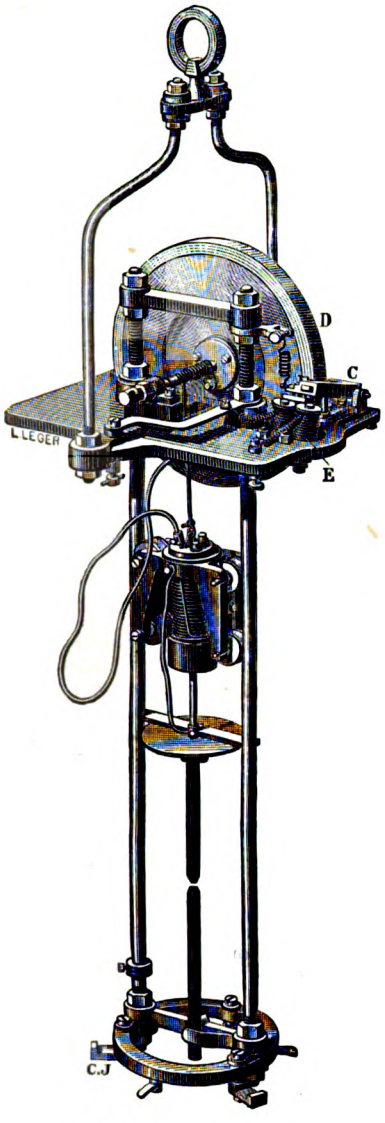
The Abdank-Abakanowicz arc lamp consists of two totally separate pieces of apparatus, namely, the lamp proper, and a sort of relay placed within reach of the hand. The upper carbon is suspended from a cord wound round the axle of a heavy fly wheel, D, which is braked by C. The brake C forms part of the armature of an electro-magnet, E, which is arranged as a shunt across the lamp terminals. Whenever the carbons become too far apart the relay sends the current through E for a fraction of a second, and the fly-wheel being momentarily unbraked rotates and brings the carbons together. The fly-wheel being relatively heavy, it moves very slowly at first, and as the brake is almost immediately applied again, the *vis viva* of the fly-wheel is soon annulled. If the motion is not sufficient, the fly-wheel is freed a second or third time. When the relay is in proper order, D is practically always in motion, and the carbons approach each other continuously.

This heavy fly-wheel is a very simple and effective substitute for the complicated clockwork found in so many lamps. The frame containing the upper carbon-holder comprises an electro-magnet which strikes the arc. The relay which is, as we have stated above, quite distinct from the lamp itself, comprises (i) a differentially wound electro-magnet the armature of which actuates a switch, which turns the current into the coils of the electro-magnet E whenever the arc lengthens; (ii) a fine wire solenoid and metallic

* Translated from M. Hippolyte Fontaine's "Éclairage à l'Électricité," by kind permission of the author.

Digitized by Google

bridge dipping into mercury, intended to act as a cut-out in case of accident; (iii) a switch for introducing a resistance into the circuit equal to that of the arc, whenever it is required to temporarily shut down the lamp.



Abdank-Abakanowicz Arc Lamp.

Although but little used, the Abdank-Abakanowicz lamp is a most ingenious one, and it worked very well at the Vienna Exhibition of 1883.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *February* 1, 1890.

Electrical Insurance.—It has now been proposed to organise and incorporate a company under the name of the Electric Mutual Insurance Company, which shall insure electric light and power stations through the United States, and possibly in Canada, against loss or damage by fire. The movement has been on foot for a long time, but has never taken definite shape till now, and it seems likely that it will be carried to a successful issue. It is estimated that in this country there are over 1,000 central stations, with a probable average valuation of no less than $25,000 each, making, on a moderate valuation, an insurable valuation aggregating $25,000,000. This novel and hopeful scheme, which has the endorsement of the Manufacturers' Mutual Insurance Companies of New England, has also the hearty approval of the Committee of the National Electric Light Association and the Insurance Committee of the Edison Association of Illuminating Companies, and it is, moreover, recommended by a large number of leading men in the electric lighting industry, including Mr. Edison, Prof. Elihu Thomson, Mr. Frank Morrison, Prof. Anthony, and many others. It is hoped and believed that the company will be a success from the start, and the indications of its success are already numerous. The exactions to which some of the companies have been subjected have for some time past been almost unbearable, and it has been only a question of time when this scheme would actually strike root, as it has now done.

Electric Welding.—It is more than likely that the development of electric welding will be attended with the discovery of a large number of new phenomena, the new applications leading, in fact, to the upgrowth of a distinctly new class of inventions. In such a category belongs the idea or principle the discovery of which is claimed by Mr. C. L. Coffin, of Detroit, and for which he has just secured a patent. The inventor proceeds in the regular way of electric welding by pressing the ends of the pieces together, but instead of relying merely on the resistance of the contact to generate the welding heat required, he claims to have discovered that by subjecting the joint to the influence of a magnet acting across the path of the current, the electrical resistance of the joint is secured, and the heating effect of the current is enhanced. He also finds that after the two pieces have been joined together a better weld may be obtained by ceasing to press the joint together, and, on the contrary, by applying stress tending to separate the joint while the current is passing—taking care, however, not to rupture the weld. This action, he asserts, increases the electrical resistance of the joint, and necessarily increases the heat again. This process is only applied for a short time, and the joint is finished as usual by rolling or hammering. I may mention incidentally that the Thomson-Houston welding process is now regularly recognised as a valuable addition to the arts here, and is being applied to a great many industries.

The Electric Motor Business.—An interesting review of the electric motor situation, and of the relation of the electric motor business to the electric lighting companies, has just been made by Mr. W. H. Fitzgerald, of Detroit, one of the pioneer electric lighting superintendents in this country. Mr. Fitzgerald, who has recently made an investigation on the subject, states that he finds there are to-day in operation in the United States stationary motors taking from 5,000 to 10,000 horse-power of current, probably near the upper limit, and about 6,000 to 8,000 small motors of one-eighth to one-tenth horse-power running sewing machines, fan outfits, &c. The confidence of the public in the electric motor is made more evident every day by the inquiries from shops and factories using from 20 to 100 horse-power, and even higher. He mentions many factories employing electric motors, such as one at Harrisburgh with 200 hands, one at Detroit with 140, and one at New York with 200, besides the factory of the C. and C. Motor Company with 150 hands, which is operated by its own motors. To this list, which might be made much longer, I will only add one other instance, that of a plant in Chicago, where a 40 horse-power Thomson-Houston motor was put in at a moment's notice to run a large printing-office where the steam plant had suddenly broken down, and where the necessary repairs and refitments with steam would have taken two or three weeks at the least. Mr. Fitzgerald, as the result of a long experience with different classes of motors, expresses himself in favour of the constant potential motor, and of circuits not exceeding 500 or 600 volts. He advises his colleagues to secure large power users, and to sell the power cheaply. He advises the companies also to control the motor sales or their rentals themselves, and he considers it a mistake where the central station takes no hand in the sale of the motors, affecting injuriously the customer and consumer alike. "Where there are three and four, and sometimes more motor salesmen in a town, by the time a prospective buyer has had a call from them all, he is ready to believe that a motor may be made either of iron or green cheese, and that the electric light company will sell him amperes by the bushel and volts by the long ton, and is generally demoralised, and as a result buys a gas machine." Mr. Fitzgerald also makes some interesting observations as to the price at which the central station can

Digitized by Google

afford to sell power, and says that prevailing records justify the statement that in a factory contracting for 50 horse-power in motors at the rate of $50 per year per horse-power, not over six-tenths of this power will be used on an average, so that the company would actually have to deliver to the customer not more than 30 mechanical horse-power. The receipts from such an installation would be $2,500, or a profit of $841, equal to $28 per horse-power on the power actually delivered. Hence Mr. Fitzgerald considers that as a general thing $50 or $60 per year per horse-power, based on the indicated horse-power of the motors, is a fair price at which to sell electric motors in units above 20 or 30 horse-power.

The Lighting of the Chicago Auditorium.—As an instance of the manner in which some of our larger buildings are now being lighted up with electrical apparatus, note may be made of the Chicago Auditorium, which is believed to be the finest building in America, and therefore we may say, with our characteristic modesty, the finest of the kind in the world. This building, which is intended to be, in the amusement line, what Whiteley's great emporium is in that of clothing and general supplies, has a dynamo plant with a capacity of 12,550 Edison 16 candle-power lamps. These lamps are distributed all over the house, and some remarkable lighting effects are obtained with them before the stage and behind it. The electric current is also used for power purposes. There are employed for ventilation three Thomson-Houston motors of 5, 7½ and 15 horse-power; three C and C motors of the same capacity, and two Eddy motors of 10 and 15 horse-power, making a total of no less than 80 horse-power of motors. Electric motors run the bellows for the grand organ, and this organ, again, is operated electrically, there being miles of wire in its circuits.

The Young Circuit-Breaker.—Some of the recent accidents occurring with broken live wires have drawn attention to the desirability of having some apparatus that would render the circuits harmless to those who are by accident or necessity brought into contact with the wires. The broken ends of a live wire may also fall across the ends of other conductors or on tin or corrugated iron roofing, and maintain a circuit practically complete, producing dangerous crosses. To avoid this trouble has been the object of several inventors recently, and a very excellent and practical device has just been brought out by Mr C. G. Young, by means of which the circuits are rendered harmless in case of rupture. Mr. Young's circuit-breaker is composed of two single electro-magnets, the bobbins of which are of metal. One end of the wire with which the magnets are wound is permanently connected to the metal bobbin, while the free end is carried to the binding posts. At the bottom of the magnets are circuit-breaking levers, held in position until the current is started by automatic latches. When current is generated by the dynamo, the magnets so influence their armatures as to maintain the circuits to line complete; but should the line become cut or broken from any reason whatever for one instant only, the magnets immediately become demagnetised, the levers drop from contact with the magnet cores, and the circuits to the dynamos are instantly ruptured at two points. Such devices as this should, I think, be put upon every arc light dynamo in the country. The mere fact of its presence, and its cutting out the dynamo as soon as the necessity arises, would tend to make the station superintendent more vigilant in the supervision of his exterior circuits, and with circuits thus protected there would certainly no longer be the insane fear which now possesses so many people as to any kind of wire whatsoever.

PARIS NOTES.

(FROM OUR OWN CORRESPONDENT.)

February 11, 1890.

Several of the central stations in Paris are of interest, owing to the peculiar systems of distribution employed. Take, for instance, the generating station situated in the cellars of the Bourse du Commerce. The engines are driven by compressed air, at a pressure of 7 kilogrammes to the sq. cm. (100lb. to the square inch), from the compressed air station in the Rue St. Fargeau, some four kilometres distant. These engines drive dynamos, which charge accumulators, and the accumulators finally supply current to the lamps. It does not require much knowledge to see that such a system must be both costly and inefficient, and it is difficult to understand what can have been M. Victor Popp's idea in adopting it. The Société de la Transmission de la Force à Distance, is actively engaged in laying its mains and in uniting its stations in the Rue de Bondy and Rue des Filles Dieu to the new generating centre behind the Gare du Nord. At the present moment these stations supply current direct, but they will shortly receive high-potential continuous current from a station situated at Saint Ouen. This high-potential current will be employed to drive motors, which in their turn will drive low-potential dynamos. At first sight this method does not seem likely to prove as efficient as an ordinary continuous-current transformer system—such as the one which is, I believe, in operation at Ipswich.

The Conseil Municipal has decided that the Rue Baltard shall be lighted by incandescent lamps. The Rue Baltard is a fine street running across the Halles Centrales from the Pont Neuf to the Pointe St. Eustache. The current will be supplied from the municipal station, and three 33-volt 2-ampere Gérard lamps will be placed in each gas-lamp.

In the Chamber of Deputies a few days ago M. Fouquier called attention to a petition from 850 subscribers to the Paris telephone exchange, complaining of the new State management. M. Tirard, in reply, claimed credit for the French system for superiority in point of audibility. M. Fouquier, he added, had complained of the incivility of telephonists, but had said nothing about the insulting remarks frequently addressed to the girl operators by the subscribers.

An important decree relating to the establishment of provincial telephone systems has just been issued. With characteristic precision the telephone systems are divided into elementary and compound groups: the former consist of a central exchange and its sub-exchanges, the latter of a group of telephonically-connected central exchanges. A subscriber to a sub-exchange may be placed in telephonic communication with his central exchange on paying the annual sum of 10fr. per kilometre of wire connecting the two exchanges. A subscriber belonging to an elementary group may have the privilege of telephonic communication with any subscriber belonging to the compound group by paying an additional annual subscription of at least 150fr., from which, however, will be deducted the annual amount paid for connection to the central office. These charges, which are by no means exorbitant, have been calculated so as to merely reimburse the State for its first outlay. A similar plan has given excellent results in the Departement du Nord around Lille, and seems likely to greatly facilitate telephonic development in the provinces.

SCANDINAVIAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

COPENHAGEN, *February* 1, 1890.

The Christiania Telephone Company have recently increased their capital by 250,000kr., as the present capital of 500,000kr. was fully engaged. The dividend is not expected to be less than 5 per cent.

The arrangements for electric lighting at Sundswall, Sweden, are now progressing, and tenders have been received, amongst others, from the Thomson-Houston Company, through their agents, the Bell Telephone Company, Stockholm, and from the Elektriska Aktiebolaget, Stockholm. Offers of boilers, &c., have been tendered by some of the leading manufacturing engineers in Sweden, the Corporation having voted 350,000kr. for the building of a central station intended for both street and house lighting. The installation will comprise 100 arc lamps and 2,000 incandescent lamps.

The chief director for the Swedish State Telegraphs, Mr. D. Nordlander, has sent in his resignation, as he does not approve of the contemplated amalgamation of the Postal Department and the Telegraphs. Mr. Nordlander has been acting in his above capacity since 1874. The Corporation of Jönköping, Sweden, has granted the Stockholm General Telephone Company concession for 12 years to work telephones in that town under certain restrictions. The annual charge per telephone is not to exceed 50kr. (£2. 15s. 6d.), and double wires are to be used. The telephone company is also to place its exchange in communication with the telegraph office. The telephone line between Stockholm and Uddevalla, *viâ* Gothenburg and Venersborg, has now been completed. The distance amounts to 630 kilometres, but the line acts perfectly satisfactorily.

The Norwegian State Telegraphs show a material increase in the number of telegrams despatched during the past year, or at least

Digitized by Google

during the first ten months of the same, the figures for the complete year not yet being obtainable. During the first ten months of 1889 738,377 inland telegrams and 423,142 foreign telegrams were despatched, as against 642,073 inland and 397,920 foreign during the same period the previous year. The receipts for this period during 1887 and 1888 were respectively 1,186,000kr. and 1,052,000kr. During the last financial year (July 1, 1888—June 30, 1889) the estimated receipts of 850,000kr. were exceeded by 163,165kr. For the present financial year there are several votes for new telephones and telegraphs, viz., completion of the Lillehammer-Bredevouzler telephone (since opened), with eight State telephone stations; telephone between Tonsberg and Aasgaardstroud (also opened); telegraph from Sandtoro to Liland (also opened); telegraph from Södingen to Risohavn, first vote towards a line Vodsö-Mehavn.

The General Telephone Company at Stockholm has during the last year had 10,536,036 conversations, against 8,768,408 during the previous year. The same Company has informed the members of the Swedish Parliament, which has recently assembled, that members can have telephones fixed for the whole of the session at their private residences for a charge of 30kr. The offer has been received with much satisfaction, and a large number of the members have availed themselves of it.

There is no doubt that Sweden stands at the head as regards telephonic development, not only in the towns but even in comparatively remote districts. As an instance I may mention the province of Dalarne, where, owing to private enterprise and a good feeling between the different companies, the system has been very generally adopted. Through economical management expenses have been brought down to what may fairly be considered a minimum. In the Falu Telephone Company there is an entrance fee of 200kr. (1kr. = 1s. 1d.), with an annual subscription of but 15 to 20kr. The result is that even people in a very small way of business now use the telephone. That the prices would be very different ones were the telephone in that district in the hands of the State Telegraphs may be taken for granted. Nor does the telegraph in any way suffer through this widespread telephone system. On the contrary, it is the medium of conveying to the telegraph stations a number of messages which would otherwise never have been sent. It seems odd that the telephone is comparatively so little used in England, although business hours are shorter and time of much more value there than on the Continent, and foreigners visiting England cannot quite understand that Englishmen, otherwise so practical, are so much behind the former in this respect.

The corporation of Copenhagen has now published the detailed plan of their new central station. The area to be served by it is intended to have a diameter of about 6,000 feet, so that 3,000 feet will be the greatest distance from the station. As a beginning, machines, &c., will be fixed for the supply of current for 10,000 lamps, but so that it can be increased up to three times this amount. For simultaneously working these 10,000 lamps about 1,100 horse-power has been considered necessary, and the power will be supplied by four steam engines, but there is accommodation for engines up to 3,000 horse-power. The cost of the engine-house, which covers about 6,000 square feet, has been estimated at 75,000kr. The steam-engines, with pumps, fittings, &c., are expected to cost 160,000kr.; the eight dynamos will cost 170,000kr.; water-pipe, &c., 25,000kr. The cost of the boiler-house is calculated at 65,000kr.; five boilers, 103,000kr. An accumulator building large enough to contain a battery of 2,000 lamp-hours' capacity is put down at 10,000kr., and accumulators at 50,000kr. The wires will be copper, protected by concrete or iron casing, and the three-wire system has been decided on. The mains for 10,000 lamps will cost about 480,000kr. As regards later extension, the matter is simple enough as regards engines, boilers, &c., but with regard to the mains it is a different thing, and it has been under contemplation to begin with mains large enough for 20,000 simultaneously burning lamps, which would entail an additional expense of some 220,000kr. This plan has, however, been abandoned, at least for the present. In addition to the above expenses, 57,000kr. will be laid out on alteration of the building, &c., bringing the total up to 1,195,000kr. It is proposed to adopt the originally proposed charge of 8 öre per 100 watt hours (about $4\frac{4}{10}$ öre per 16 candle lamp per hour—1d. = $7\frac{1}{2}$ öre) as a basis, although a somewhat different mode of charging may be actually employed. It has not been thought advisable to leave it to the different consumers to find their own lamps, so that, to begin with, a lamp charge will be made, including a charge for renewal. The charge will be moderate, and it is thought that in time this charge might be abandoned and the lamp question left to the consumers. Lamp renewals have been estimated at $2\frac{1}{2}$-3kr. per incandescent, and it is proposed to fix the lamp charge at 4kr. per annum, including first cost and renewal, which is equal to about one-fifth öre per hour. It is proposed to take the money for this station from the renewal and extension fund of the gas works, which are Corporation property.

CORRESPONDENCE.

COST OF ELECTRIC TRACTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Inferences have been drawn from the recent statement of the Chairman of the North Metropolitan Tramway Company, that in the light of practical experience seem hardly justifiable. I would therefore beg permission to call attention in your pages to the following facts:—In the first place, Sir, it must be borne in mind that that gentleman merely announced that the cost to his own company of electric traction on the Barking-road had been $4\frac{1}{2}$d. per car mile. Of course the ordinary deduction would be that the cost to the Electric Traction Company had been less than this, but considering that several of the companies who are interested in pushing electric traction would be quite willing, in view of the difficulties in the way of making a start in this country, to work a first line at a loss, to say nothing of the chances of their unintentionally doing so, I think it is not too much to say that it is difficult to believe that there can have been any real profit to the Traction Company in the undertaking. I do not mean to say that it is impossible to work by electricity at this cost, as with the overhead conductor, or even with the expensive underground channel (on short lines with heavy traffic), it is perfectly practicable; but I do say that with accumulator systems, such as the one in use on the road in question, it is impossible at this figure to make adequate provision for the maintenance and renewal of the secondary cells employed. For an experiment of six months or so all may look well, but it is certain that at least 30 per cent. per annum must be allowed for depreciation on accumulators subjected to such rough usage (both from an electrical and from a mechanical point of view) as is bound to fall on them when used for electric traction. When one considers that, in addition to this enormous depreciation, the efficiency of the accumulators cannot possibly in practice exceed, say, 70 per cent., it is not difficult to see why the storage battery system must be dearer than the direct supply by a fixed conductor, except in those cases where the line is very long and the traffic light, so that a small return only is secured on the capital laid out on a lengthy conductor.

The truth of this assertion is completely borne out by the only definite figures hitherto published as to the cost of traction by accumulators for any practical length of time, viz., those derived from the working of the Brussels tramway (*The Electrician*, August 16, 1889, p. 386). Here the Julien system has been in use for $2\frac{1}{2}$ years, and the cost of maintaining the accumulators, estimated at about $\frac{1}{2}$d. per car mile, turned out in practical working to be $1\frac{1}{2}$d.; maintenance of motors and gear nearly another 1d., these two items together making nearly $2\frac{1}{2}$d. per car mile, and the total expenses of running, without counting wages, maintenance of engine, depreciation of fixed and rolling stock, and interest on capital, amounted to over 4d. per car mile. Considering that the wages of drivers alone come to about $\frac{1}{2}$d. per car mile, the public are quite justified in believing, until the production of some proof to the contrary, that the $4\frac{1}{2}$d. per car mile charged by the Electric Traction Company, if it represents anything at all, includes only the immediate out-of-pocket expenses, and does not cover a due allowance for maintenance and depreciation.

With apologies for trespassing so far on your valuable space,

Yours, &c., H. J. S. HEATHER.

18, Stanley-road, Wimbledon, February 10, 1890.

MR. KAPP'S REPORT ON THE ARON METER.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have read with great interest Mr. Kapp's report on the Aron meter, and your remarks on it. As I have had considerable experience of meters of various types, I trust you will pardon me for offering a little criticism on the report in question.

First, let me say there are two obvious misprints. In the direct current test with 23 amperes, the constant should be 1·13

Digitized by Google

instead of 1·30, and in the alternating test with different ∿s it should be 1·195 instead of 1·95.

Passing over these printer's errors, I would ask Mr. Kapp whether he considers a four-fold range sufficient for a meter to be fairly accurate over. There are meters in the market, which for obvious reasons I will not name, that have identical constants at 10 amperes and 100 amperes, or 6 amperes and 60 amperes.

As an instance of what a meter *can* do, I may mention one that has been at work since December 3, 1887, continuously (with the exception of a few days when it was taken out of one consumer's installation and put in at another's), and is still working satisfactorily. The constant was determined at 1·9 amperes, at 95 amperes, and at four intermediate points, and the extreme variation from the mean was 0·1 per cent. This, it will be observed, is a fifty-fold range.

In order that a test should be thoroughly satisfactory, at least five or six points should be determined on the curve connecting current and constant; for it is an easy matter to adjust a meter so as to have the same constant at two given points, but not so easy to get the line joining them straight.

We must hope in the interests of consumers that it is not of importance for the meter to be accurate with varying P.D.'s for a mean pressure whose limits are 95 volts, and 130 volts is not a cheering prospect to any but lamp makers.

As regards the regulation of the Aron meter, it is satisfactory to learn that it is so easy, for I believe it is not impossible for the controlled pendulum to stop, and in a few hours undo the work of many days. I believe it to be a fact well known to clockmakers that no matter how carefully a clock may be regulated when it leaves their hands, it always requires adjusting *in situ*. This applies also, I have been told, to Aron meters, and would appear to be a serious disadvantage, since a considerable time is necessary for a small difference in the rate of the pendulums to show, so that several journeys are necessary for the man installing it; moreover, once an adjustment is altered, one cannot feel certain that the constant determined before the adjustment was made is still applicable. Indeed, Mr. Kapp's report shows the effect on the constant of the adjustment he made.

Apologising for the length of this letter.—Yours, &c.

A. K. C.

TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning.*]

"THE ELECTRICIAN"

ELECTRICAL TRADES' DIRECTORY & HANDBOOK for 1890

The new edition of our well-known Directory and Handbook is now ready. The book consists of 850 pages, and has entailed this year an exceptionally heavy amount of work. The HANDBOOK DIVISION contains a mass of most useful information. The DIRECTORY DIVISION consists of more than 400 pages, and contains a very carefully compiled Alphabetical and Classified List of Firms and Persons engaged in the Electrical and Allied Trades in all parts of the world. This Division has been corrected up to date, and the book is thoroughly reliable, even the very numerous changes which take place in the month of January being incorporated. By the aid of this Directory, makers of Electrical Machinery, Apparatus, Instruments, Fittings, Sundries, Novelties, and other goods, may safely communicate direct with probable customers without the annoyance and great expense consequent upon using books which are mere lists of Members of Scientific Societies repeated again and again. A large number of copies have been already subscribed for from the Colonies, the Continent, the United States, and other Foreign Countries, whilst at Home orders have been received from Local Authorities, Railway, Tramway, Mining, and other large Industrial Corporations, as well as from those for whom the Directory and Handbook is primarily compiled. The Colonial and Foreign Division will be found extensive and reliable. *Orders should be forwarded at once.*

PERSONAL.—Mr. Holland Dell, for many years secretary to the Electrical Power Storage Company before the amalgamation with the Electric Construction Corporation, has been appointed sole representative for the United Kingdom and Colonies, of the well-known Paris carbon manufacturers, Messrs. Lacombe and Co. Mr. Dell's offices are at 7, Little Queen-street, Westminster, S.W.

MESSRS. WOODHOUSE AND RAWSON UNITED (LIMITED). — This Company are about to wire the premises of the Hansard Publishing Union in Russell-court, and the current will be supplied from the Sardinia-street Station of the Metropolitan Company. In addition to glow lamps, two 30-ampere arcs will be installed to assist in the work of photo-engraving by the Vanoni process.

AWARD.—At the recent International, Electrical, and Industrial Exhibition, held at Birmingham, Messrs. Robey and Co., of Globe Works, Lincoln, were awarded a special first-class gold medal for their high-speed engine fitted with patent electrical regulator.

THE "ELECTRICAL WORLD" OF NEW YORK.—Our enterprising contemporary is circulating in the form of a folio pamphlet an illustrated description of the large new offices recently taken in the Times building, New York. The text of the pamphlet shows that the *Electrical World*, like most technical and trade journals, has had its serious ups and downs, but from the lively way in which the history of the paper is written, and from outward and visible signs generally, we gather that in 1890 the paper continues its successful career. As European agents for the "World," we can speak with some authority of the very considerable sale the paper has in this country and on the Continent, and we feel sure that the enterprise shown in distributing broadcast the interesting particulars above referred to will reap its reward in a considerable addition to its already long list of British and Continental subscribers.

ELECTRIC LIGHT AND POWER RISKS IN AMERICA.—We have received a prospectus of the Electric Mutual Insurance Company of Boston, Mass. From this we learn that it is proposed to organise and incorporate a Company for the purpose of insuring electric light and power generating or distributing stations throughout the United States against loss or damage by fire. The prospectus states that it is difficult to obtain insurance on electric lighting and power property owing to the lack of knowledge on the part of fire underwriters as to the fire hazard of this class of risk, and that a universal demand for insurance at reasonable cost exists throughout America. There are in the United States over 1,000 central stations, with a probable average valuation of not less than £5,000, making an insurable value aggregating £5,000,000. It is proposed to begin with a maximum of £5,000 on a single risk, and reduce that line according as the risk varies from the standard. In New England there are 100 acceptable stations on which it is believed an average of £3,000 insurance will be at once effected. It is proposed to maintain a system of inspection similar to that established by the large fire risk Corporations, and bureaus of inspection will be established in all the large cities of the Union, giving each station as many examinations per year as may be thought advisable by the Directors. For this purpose a sufficient number of skilled inspectors will be employed. In conclusion, the prospectus states that in addition to the expectation of a materially reduced cost of insurance, great benefit will accrue to the owners of electric light and power stations from the periodical visits of competent inspectors, who will be expected to give each Company advice and instruction as to reducing the fire hazard. The prospectus is endorsed by a large number of gentlemen well known in electrical circles in America, including J. F. Morrison, S. A. Duncan, Prof. Elihu Thomson, Thos. A. Edison, Wm. A. Anthony, Otto A. Moses, Allen V. Garratt, Allen R. Foote, C. D. Morse, and about 60 others.

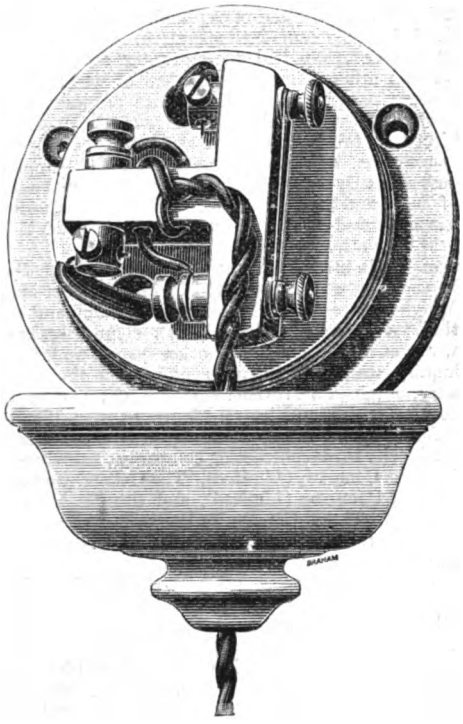
BINSWANGER'S HIGH INSULATION CEILING ROSES.

The use of ceiling roses has become very general for electric light installations of every kind. Both in the factory and in the drawing-room they are employed as the most convenient, safe, and artistic attachment of pendants to the mains. Since they were first introduced, like all other electrical fittings, they have had to undergo a great many changes. A good ceiling rose should be fireproof, easily wired, strong enough for carrying weight, for which purposes no contact pieces should be used, should have plenty of room for a cutout, and the whole construction should be such that dampness of the wall should not affect its insulating properties. The illustration shows the latest type designed by Mr. G. Binswanger, and manufactured by the General Electric Company.

On the top of the china base are walls projecting in the shape of a T, to which the terminals are fixed in such a way that no brass parts of any kind are visible at the back of the ceiling rose. Two holes leading through these walls are for the purpose of separating the flexible wire in the manner shown above, thus making it

Digitized by Google

possible to connect considerable weight to the ceiling rose without strain on any of the contact pieces, while the wire is also separated at the base so as to meet the requirements of insurance companies. The terminals are very substantial, and there is 1¼in. space for the cutout, which is constructed for the use of tin or lead wires with or without eyelets.



The Binswanger Ceiling Rose.

We are glad to see that manufacturers are now paying such great attention to these small fittings, which contribute so largely to the proper working of an electric light installation.

LEGAL INTELLIGENCE.

Blackburn v. the Lancashire and Yorkshire Railway Company.

The above was an action brought before Deputy-Judge Wright in the County Court by R. S. Blackburn, electrical contractor, carrying on business at Hebden Bridge, against the Lancashire and Yorkshire Railway Company for £2. 10s. 1d., for damages alleged to have been caused under the following circumstances.

Mr. SHAW, who appeared for the plaintiff, said that in the month of April last plaintiff undertook a contract for the construction of a telephone line at Newhey, near Rochdale, and about 22 miles from Halifax. For the purpose of the work he ordered from a firm of wire manufacturers in Halifax, a quantity of copper wire with instructions to forward to Newhey railway station. This wire, which was required on the following morning, was despatched from Halifax on the 24th of April, but was not delivered until the 27th. The result of this delay was that a number of men engaged by the plaintiff were unable to proceed with their work, and expense was incurred in railway fares, wages, &c., the total amounting to the sum now claimed. Mr. Shaw contended that this delay was unreasonable for such a distance of transit. In fact, if it had not been for the negligence of the company's servants in miscarrying the wire to Oldham instead of placing it down at Newhey station, as addressed, the goods would have been delivered at the proper time.

Mr. STOREY (who represented the Lancashire and Yorkshire Railway Company) for the defence said that the goods in question were sent at "owner's risk," and at the lowest freight. He contended that no negligence on the part of the defendant company had been proved, and as the goods had to be twice transhipped, the delay was not unreasonable. He contended that it would be monstrous to saddle a railway company with damages under such circumstances as those.

The DEPUTY JUDGE thought there was not sufficient evidence of negligence to entitle plaintiff to a verdict. It was true the goods were sent at "owner's risk," that was at the lowest rate at which goods were carried; but if he had been satisfied that there had been negligence, the fact that the goods were sent at "owner's risk" would not have prevented him from giving a verdict for the plaintiff. Although the goods were a long time in transit for so short a distance, there was no evidence of negligence, and the delay, for anything he knew, might have arisen from an accident or a mistake in transhipment. There would be a verdict for defendants.

COMPANIES' MEETINGS & REPORTS.

Chelsea Electricity Supply Company (Limited).

The ordinary annual general meeting of this Company will be held at their Central Station, Draycott-place, Sloane-square, London, S.W., on Wednesday the 19th inst., at 12 o'clock noon, at which the following report of the Directors will be presented :—

Up to May, 1888, when the last report was issued, the Company had only been able to take preliminary steps for its development. In July of that year the Electric Lighting Bill, introduced to Parliament by Lord Thurlow, having passed both Houses, the Board of Directors was re-formed, and a prospectus was published. The capital requisite to proceed with the construction of a generating station, and to put down the necessary plant for the distribution of electricity within the first area of supply, as included in their Act, was then obtained. The necessary contracts for building and plant having been made, work was commenced in the latter end of 1888, and in an unprecedentedly short time the central station was completed, under the supervision of the Company's architect, Mr. F. G. Knight, of 6, Great College-street, Westminster.

Early in April, 1889, the station was so far ready that experimental plant was put to work, but owing to a delay in supplying the engines arising out of the destruction by fire of the works of Messrs. Willans and Robinson, of Thames Ditton, and several other causes, the period of experiment and preparation continued until the end of September, after which the work of regular and extended supply came into operation.

At the outset the Company had to encounter competition within its area of supply of two other Companies, neither of which were operating under Parliamentary powers. These Companies proposed to invade the district with overhead lines, and take advantage of the uncertainty of the law on the subject to obtain some custom at a comparatively small outlay. By strenuous opposition, by actively pushing on the completion of its works, and by subsequently entering into a friendly arrangement (approved by the Board of Trade and the Chelsea Vestry) with one of those Companies, the Company has succeeded in neutralising any effect which this desultory competition might have otherwise had on its business.

At the Board of Trade inquiry held at Westminster Town Hall in March and April, 1889, the Company, represented by Mr. Fletcher Moulton, Q.C., and Mr. R. S. Wright, successfully defended its position, and succeeded in showing that the system it had adopted, now commonly known as the Chelsea system, was at least equal to any other system under inquiry. One result of this inquiry was, that the Company, with the consent of the Kensington Vestry, obtained a Provisional Order for a part of that parish, known as the South Kensington Electric Lighting Order, 1889.

The contracts for the plant to extend the system into Kensington, were again undertaken by the three contracting companies, namely :—The Brush Electrical Engineering Company (Limited), The Callender's Bitumen Telegraph and Waterproof Company (Limited), and the Electric Construction Corporation (Limited). These Companies agreed to receive payment in fully paid-up shares of the Chelsea Company. Since early in December current has been supplied in South Kensington.

The Company has obtained the sanction of the Board of Trade, and of the Chelsea Vestry, to extensions of their area of supply on the south, and on the north of their first area up to Knightsbridge, including the Lowndes-square district. They have nearly completed the erection of a fourth storage station at the northern end of Pavilion-road, and have made all the arrangements for laying down the necessary mains throughout those areas.

In the erection of the Company's central station, the Directors were obliged to provide a building of sufficient capacity for all probable future demands and extension of area of supply. The building includes space for a generating plant to supply a total of 30,000 (8 to 10 candle-power) lamps in use at one time, representing a total of 60,000 installed. Besides, it contains one storage station, the necessary offices, and residential accommodation for some of the staff. The outlying storage stations of the Company in use, or about to be put to use, are in Clabon-mews, Pavilion-road, and Egerton-gardens, and negotiations are in hand for a fourth.

The Company has received many testimonials from its customers, expressing the most marked approval of the system of supply. The causes for this satisfaction continue, and they may be chiefly traced to the perfect steadiness of the light, and the consequent economy of wear and tear of glow lamps, and total absence of any interruptions to the light which the system secures.

The steady and gratifying growth of the Company's business is exemplified by the following statement showing actual cost (exclusive of general charges) of running machinery and storage stations, and the revenue received for current supplied during the three months ending December 31, 1889. The table shows the relation between running and revenue expenses in the months of October, November, and December, 1889, being the first regular quarter, and bears remarkable evidence of the proportionate increase of income, as compared with expenses as custom extends.

In order to complete the works in hand, and to be ready to meet the cost of the necessary extensions, the Directors seek the approval of the shareholders to the creation of debentures to the amount of £50,000.

The retiring Directors are Major-General Webber and Mr. Daniell. who, being eligible, offer themselves for re-election. The auditors, Messrs. Cooper Brothers & Co., also offer themselves for re-election.

The following resolution will be proposed at the meeting:—

"*That the Directors be, and they are hereby, authorised to borrow a sum not exceeding £50,000, and to secure the same by the issue of Debentures in such form, secured in such manner, and issued to such persons on such terms and at such times as the Directors may deem expedient.*"

NEW COMPANIES REGISTERED.

THE ELECTRICAL ENGINEERING CORPORATION.—The prospectus of this Company has been issued this week. As our readers are aware, it is an amalgamation of the firms of J. G. Statter and Co. (Limited) and the United Electrical Engineering Company (Limited). The capital is £150,000, in 29,600 ordinary shares of £5 each, 400 founders' shares of £5 each, and £20,000 in 200 Six per Cent. Mortgage Debentures of £100 each. The present issue is £77,000, in 15,000 ordinary and 400 founders' shares of £5 each, of which 15,000 ordinary shares are now offered for subscription at par, together with £20,000 Six per Cent. Mortgage Debentures, as a first charge. The electrical engineer is Mr. Sydney Linton Brunton, Assoc.M.Inst.C.E., Assoc.M.Inst.E.E., and the secretary Mr. Percy E. Scrutton.

FAREHAM ELECTRIC LIGHT COMPANY (LIMITED).—The prospectus of this Company was issued yesterday (Thursday). The capital is £5,000 in £1 shares, of which 1,600 are offered for public subscription, payable 5s. on application, 5s. on allotment, and the balance as may be required, subject to one month's notice. The directors are S. R. Delme, Esq., Cams Hall, Fareham; Capt. J. Ramsey, R.E., Yvery House, Fareham; Admiral S. P. Townsend, Osborn-road, Fareham; James Blake, Southfield House, Fareham. On the completion of the company the shareholders will be asked to elect three directors. The Laing, Wharton and Down Construction Syndicate are the electrical engineers. The prospectus states that the Company is formed for the purpose of supplying electricity both for public and private lighting, and also for motive power in the town of Fareham and its vicinity. It is proposed to use the Thomson-Houston system. The list of applications for shares opens on Monday next, and close on Monday, March 3.

LANE FOX ELECTRICAL COMPANY.—OBJECTS: To carry on the business of electrical engineers, electricians, practical engineers, contractors and manufacturers of apparatus for producing and supplying light, heat, sound, and power by electricity or magnetism. Capital £100 in £1 shares, which are fully subscribed for by St. George Lane Fox, electrical engineer, 50, South Eaton-place, 70 shares; Charles Arthur Stephenson, electrician, 90, Inverness-terrace, 2; Walter John Grove, J P., Salisbury, 2; Bernard Drake, electrical engineer, 60, Victoria-street, Westminster, 5; John Marshall Gorham, electrical engineer, 66, Victoria-street, 5; William Lane Fox Pitt, 4, Grosvenor-gardens, 12; and F. J. Cobden Sanderson, barrister, Hendon. Vote per share. First directors (three to ten), the subscribers above-named. Remuneration £1 each per attendance, and 7 per cent. of profits available for dividend to be divided proportionately. Borrowing limit, £5,000. Registered February 6th, by Waterlow Brothers and Layton (Limited), Birchin-lane.

THE MUTUAL TELEPHONE COMPANY (LIMITED).—Registered by Rowcliffes, Rawle and Co., 1 Bedford-row, W.C., with a capital of £100,000 in £10 shares. Object, to carry on any business relating to telephones or telephone apparatus, or any business which may be advantageously carried on therewith. The first subscribers are:—W. D. Provand, 9, Bridge-street, Westminster; G. Hahle, 100, Portland-street, Manchester; H. T. Gaddum, 57, Brown-street, Manchester; E. Guthrie, 71, King-street, Manchester; W. Thomson, 79A, Princess-street, Manchester; W. Mallison, 105, Princess-street, Manchester; E. A. Hague, 6, Dickinson-street, Manchester; W. Wadsworth, 4, Albert-square, Manchester; A. Forrest, Hoet Town, Manchester. There shall not be less than five nor more than 15 Directors, the first to be appointed by the subscribers to the memorandum of association. Qualification, 10 shares. Remuneration to be determined in general meeting.

UNIVERSAL ELECTRIC LIGHT AND POWER TRUST CORPORATION.—Objects: To invest moneys in and acquire shares, stock, debentures, and securities of any company, trust, or corporation at home or abroad, and in particular such as pertain to the supply of electric light, heat, or power for public or private purposes, and to promote and assist enterprises of a cognate character. Capital, £5,000, in £10 shares, of which 400 are founders' shares, the remaining 100 being ordinary. Founders' shares to receive one moiety of surplus net profits, after 8 per cent. dividend. Registered, January 28, by T. H. Harvey-Samuel, solicitor, 1, Whittington-avenue.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended February 7th amounted to £5,014.

BRUSH ELECTRICAL ENGINEERING COMPANY.—In view of the satisfactory volume of business transacted during the past six months, the Directors of this Company have decided to pay an interim dividend upon the preference shares of this Company, and warrants for a dividend on these shares at the rate of 6 per cent. per annum from August 10, 1889 (the date of registration of the Company), to February 10, 1890, will be issued on the 1st proximo. As the books of the Company will not be made up until the close of the year, the Directors defer the question of a dividend on the ordinary shares until the complete accounts are before them. The transfer books of the Company as regards the preference shares will be closed from the 15th inst. until the 1st proximo.

ELECTRICITY SUPPLY COMPANY OF SPAIN.—There is a call due this day (Friday) of 30s. per share on 19,900 shares of this Company.

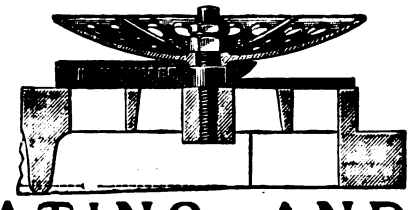
SHANGHAI ELECTRIC COMPANY.—The new Shanghai Electric Company (Limited) has paid a dividend of 7 per cent. for the year ended October 31st last—the first year of its working.

TAUNTON ELECTRIC LIGHTING COMPANY.—At the annual meeting of this Company held on Monday, the 3rd inst, at the Castle Hotel, Taunton, the Chairman moved that the report be adopted, and that a dividend of 5 per cent. free of income tax, be declared. He said that early in the year the Directors gave their careful consideration to the procuration of a new site for their depôt, and they secured by public auction a piece of land, situated very near to the Gas Company, but owing to the recent disastrous flood, which rendered their purchase useless, they went to considerable expense in building arches upon which to erect machinery. Under these circumstances they had bought a piece of land which, he believed, would serve their purpose admirably, being in nearly the centre of the town. They had now nearly completed their depôt, and the shaft was a land mark which could be seen a long way round Taunton, serving as a valuable advertising medium. The work of laying down the machinery was in progress, and they hoped in two or three weeks they would be in full working order.—The report was adopted, and Mr. Fowler, Mr. C. E. Lance, and Major Winter were re-elected Directors.—Mr. Down (of the firm of Laing, Wharton, and Down) stated that his firm last week got the contract for lighting one-half of the streets of London and the monopoly of private lighting. He expected they would get the contract the next day for lighting another town about as large as Taunton. He congratulated the Company upon the valuable site they had secured.—Mr. Massingham proposed that "in future years the annual general meeting of the Company be held any time during February that the Directors might think fit," which was carried. A vote of thanks terminated the proceedings.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended February 7th, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited), were £3,804.

NEW VALVE

No Rubber, Percha, or Leather.



One-half the price of Rubber or Metal.

FOR CIRCULATING AND AIR PUMPS.

Unaffected by any Lubricating Oils. Does not Expand in diameter. Feed Water may be worked at any temperature Suitable for any shaped guards. Only one quality manufactured.

"12, John-street, Sunderland, 26th Sept. 1885.

"DEAR SIRS,—In reply to your letter of the 25th inst., the Valves I got from you have done their work well, and ARE AN UNQUALIFIED SUCCESS. I will continue to get them from you as required.—Yours faithfully, JAMES WESTOLL."

For further Testimony and Prices, apply to **MOSSES & MITCHELL, 68-71, Chiswell Street, London.**

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 614.—Vol. XXIV. FRIDAY, FEBRUARY 21, 1890. Price Fourpence.

NOTES.

Mr. Swinburne's Paper on "The Theory of Armature Reaction in Dynamos and Motors," read before the Institution of Electrical Engineers on the 13th inst., will be discussed conjointly with Mr. Esson's communication on "Some Points in Dynamo and Motor Design," read last night.

The simplicity introduced into dynamo and motor design, by considering the subject from the magnetic circuit point of view first suggested by Hopkinson and Kapp, has received fresh exemplification in Mr. Swinburne's valuable Paper. The analogy between the electric and magnetic circuits is still further brought out by the use of the term magnetic potential. The magnetic circuit can thus be considered in parts, just as the currents in each branch of a network of conductors can be determined separately when the electric potentials and resistances are known. The investigation of magnetic leakage is thus rendered clearer. There is, however, no justification for using the erg as the unit of magnetic potential.

The reaction of the armature on the field is very simply described by resolving it into two components, one of which opposes the field by creating a back-induction, while the other creates a cross-induction. In this way the weakening effect on the magnetism of parts of the pole-pieces and its strengthening effect on others is shown in a simple and novel manner. An explanation is also given of the greater amount of sparking occurring at the lower brush of single-magnet Gramme machines.

Mr. Swinburne is probably right in considering that one of the greatest problems yet remaining in the construction of direct-current dynamos is how to avoid sparking at the brushes and the consequent wear of the commutator. In order to avoid the sparks due to the currents maintained in the coils by self-induction, Mr. Swinburne suggests several means for introducing extra electromotive forces opposing the self-induced ones. The confident remarks of the author with regard to the relations between dynamos and motors will certainly arouse a great deal of discussion, as much difference of opinion exists on this point among the best judges, both practical and theoretical. The divergences from perfect reversibility of dynamos and motors are mainly due to the complex armature reactions, and whether these are of much relative importance or not depends chiefly upon the dimensions of the machine.

In connection with the subject of magnetic potential, we may remind our readers that a very simple and convenient instrument for its measurement was described before the Physical Society of London some time ago by Mr. A. P. Chattock. This instrument consists of a long solenoid of many turns wound on an elastic core so as to be flexible. One end of this helix is kept fixed while the other is moved quickly between the two places whose difference of magnetic potential is required. The ends of the coil are connected with a ballistic galvanometer and the impulse imparted to the needle is a measure of the potential difference required. This instrument might be useful in measuring the quantities referred to by Mr. Swinburne, and it seems clear that some such instrument would be of use in dynamo tests and in dynamo design.

The twenty or thirty persons who comprised Mr. Henniker Heaton's audience at the Society of Arts on Tuesday afternoon were evidently too deeply concerned with the cheapening of ocean postage rates to pay much heed to his theories concerning telegraph cable rates, or to criticise too nicely the manner of his advocacy. People, however, who can be got to a five o'clock meeting of that kind are mostly enthusiasts, and may perhaps be excused for patiently, though silently, listening to Mr. Heaton's malignant insinuations against unnamed opponents. The Chairman was apparently the only person to realise the compromising position in which the reader of the Paper was placing the Society. Addressing the meeting at the conclusion of the discussion, Sir Francis Bell remarked that it was not to be expected that all would agree with views put forward on that platform, but so long as they were expressed with moderation and fairness, the Society was always ready to give them a hearing.

We cannot help thinking from this and other indications that the Chairman's ideas of moderation and fairness had been somewhat shocked by various passages in Mr. Heaton's address, and we shall be much disappointed if some of them are not eliminated before the Paper gets published in the Society's *Journal*. The Society cannot guard against its privilege being abused, once at least, by a reckless and intemperate orator, but it can prevent its *Journal* being made the medium for disseminating his gratuitous slanders. What he said of the Post Office and its principal officials was bad enough, and would hardly have been tolerated even in the House of Commons; but of the cable companies, especially of

Digitized by Google

one of them, and of the leading man amongst them, Mr. HENNIKER HEATON'S language, if not the result of that stupid vanity which mistakes extravagance for eloquence, must have been dictated by pure malevolence. Mr. HEATON may consider himself lucky that he had not a larger and more discriminating audience; and we shall be much surprised if he is ever again allowed the chance of addressing one, great or small, at the SOCIETY OF ARTS.

IN the *Electrical World* for February 1st is described an arrangement devised by Mr. MARK DEWEY for operating a series traction system without the necessity for breaking the main circuit. The motor on the car is shunted to a portion of the working conductor, the current from which is diverted into the car by means of an opposing E.M.F. set up in the part of the wire shunted. This E.M.F. is caused by a thick cylindrical iron tube, laminated to avoid eddy currents, and carried by the car so as to be concentric with the working conductor. A longitudinal slot is made in the lower part of the cylinder so as to allow the supports of the working conductor to pass through as the car moves on. Flexible iron or steel brushes are fixed to the sides of the slot, and close the magnetic circuit of the tube by pressing together. The magnetic resistance is thus small, and as alternating currents are employed, a large amount of impedance arises in the portion of the conductor within the tube. We presume that, when the car stops, the motor is short-circuited, so that the impedance caused by the tube does not affect the main current. Alternate-current motors are preferred by the inventor, although others may be used if the alternate current is first rectified by any of the "simple well-known devices" for the purpose. What these simple methods are we should be glad to know. Ingenious as Mr. DEWEY'S method is, it hardly seems to be capable of diverting sufficient power into the car without the employment of iron tubes which would be too heavy for practical work. The arrangement may, in some respects, be compared with a transformer with only half a turn in the primary circuit, and the weight of such a converter designed to absorb power enough to drive a car would be prohibitive.

IN a somewhat lengthy letter in *The Times* of Monday, Major FLOOD-PAGE insists upon two elementary facts which have of late been somewhat lost sight of, namely, that no known system of artificial illumination is absolutely free from danger, and that a consumer who entrusts his indoor wiring to a bellhanger or upholsterer will probably consume his house rather than the electric current. As Major FLOOD-PAGE further points out, the concentration within a single State, and almost within a single city (New York), of so many of these sad fatalities tends to prove that they are due to bad work and not to any inherent danger in the electric light itself.

THE current number of the *North American Review* contains a short article from the pen of Sir WILLIAM THOMSON dealing with the overhead wire question both from the point of view of possible danger and supposed ugliness. After briefly glancing at the question as it presents itself abroad, Sir WILLIAM THOMSON states it as his opinion that if the Board of Trade regulations could be *permanently* fulfilled in every case, the protection of the public would be effectually secured. The trying nature of the English climate, however, makes the permanent maintenance of a high standard of safety sufficiently problematical, he thinks, to warrant the burying of electric light wires at least in city districts. "As for the country, telegraph, telephone, and electric light conductors must all be in the air. The cost of placing them underground would be absolutely prohibitory of the great public benefit to be obtained by placing more and more of them in the air."

IT is needless to say that Sir WILLIAM THOMSON has but scant sympathy with those "persons of taste" who find something unspeakably ugly in the "cirrus clouds of electric wire hovering perennially over the streets and houses," and he prophesies that some future RUSKIN will wax enthusiastic over the beauty of "the gossamer lines of telephone wire . . . ornamenting whatever they touch."

THE rival claims to the invention of the electro-magnet evidently contain the germs of an international imbroglio. "It seems," says *La Lumière Electrique* in its last issue, "that at the Cantor lecture delivered before the Society of Arts on February 3rd, Prof. SILVANUS THOMPSON claimed for STURGEON the honour of having invented the electro-magnet, and it seems that STURGEON exhibited a model of his invention to the Society of Arts in 1825. This claim cannot be sustained for an instant, the invention having been announced by AMPÈRE in September, 1820, before the Académie des Sciences, at Paris, after a communication by ARAGO. We shall return to these pretensions when the full report of Prof. SILVANUS THOMPSON'S lecture is in our hands."

Series Incandescent Lighting.—Mr. Alexander Bernstein has obtained a contract for the lighting of the small village of Farmsen, near Hamburg.

The Series Electrical Traction Syndicate (Limited).—This syndicate have now on hand six provincial contracts for working tram lines by electricity.

Electro-Harmonic Society.—The next concert (ladies' night) of this society will take place on Friday evening next, at the St. James's Hall Restaurant, at eight p.m. The usual excellent programme is provided.

Another Fire at the Pearl-street Station.—A Reuter's telegram in the *Daily News* of Monday states that a slight fire occurred on Saturday last at the works of the Edison Electric Light Company in Pearl-street.

Weybridge.—Several of the residents of Weybridge visited the works of the Laing, Wharton, and Down Electric Construction Syndicate last week, when the electric light was tested for the first time. All were favourably impressed.

A Carbon Disc Arc Lamp.—It is reported from Boston, U.S., that the firm of Heymann Brothers are introducing an arc lamp having rapidly rotating carbon discs in lieu of rods. It is claimed that these lamps can be run for over 40 hours without requiring carbon renewals.

Personal.—Mr. W. J. Hancock, M.I.E.E., Assoc.M.Inst.C.E., Superintendent of Telephones in the Railways Department of

Digitized by Google

Western Australia, has been appointed Superintendent of Telegraphs and Telephones in the Postal and Telegraph Department of Western Australia.

Ipswich.—At their last meeting the Town Council decided to support the Provisional Order promoted by the Brush Electrical Engineering Company. From the report of the Committee it would appear that the Brush Company intends to adopt the low tension system.

Royal Humane Society Awards to Electricians.—The Royal Humane Society has granted its honorary testimonial to Mr. A. E. Saul, third officer, and to Mr. Brown, quartermaster, of the telegraph ship "Buccaneer," for rescuing a sailor from drowning in Pernambuco harbour.

Magdeburg.—The Mayor of Magdeburg invites tenders for the erection of a central station for the distribution of light and power. Tenders must be received by May 1st, at the offices of the Gas und Wasserwerke, Spiegelstrasse 16, Magdeburg, where further particulars may be had.

An American Re-invention.—The *Electrotechnische Zeitschrift* publishes at some length a description of a "new coreless alternator," of the American Brush Company's "patent Pfannkuche." To illustrate it, however, they use three cuts of the Mordey machine, but make no mention of that gentleman.

The Schanschieff Portable Electric Lamp.—At the Königin Luise Colliery, in Upper Silesia, the Schanschieff portable primary-battery electric lamp has been tried with success. The lamp weighs 3·3lb. when uncharged, and 4·6lb. when charged, costs 30s. 6d., and costs about 1d. per hour when burning.

Messrs. Siemens and Halske.—The business of Siemens and Halske has been formed into a company, with Messrs. C. H. Siemens, at St. Petersburg, and A. W. von Siemens and G. W. von Siemens, at Berlin, as responsible directors. Offices will also be taken at Munich, principally for electric light business.

Birmingham.—At a meeting of the Electric Lighting Sub-Committee of the City Council, held on Thursday last week, it was decided to support the Birmingham Electric Supply Company, which proposes to introduce the same system as that in use at Liverpool. It was also decided to oppose any application by another company.

Folkestone.—At the last meeting of the Town Council a letter was read from Messrs. Crompton and Co., to the effect that they would undertake to transfer their Provisional Order to the Corporation on being paid their expenses up to date, viz., £225. After some discussion the matter was adjourned until the next meeting.

National Society for the Exemption of Machinery from Rating.—By the aid of Mr. Winterbotham, M.P., the Bill for the exemption of machinery from rating has been ordered for second reading on April 16th next. In order to secure the passing of the Bill it is of the utmost importance that every effort should at once be made to obtain the votes of Members of Parliament.

Lecture.—Mr. George Offer will this evening deliver a lecture at St. James's Hall, Piccadilly, in connection with the Balloon Society of Great Britain, on "The Action of Local Authorities and the Board of Trade in connection with the Supply of Electricity." Tickets may be obtained at the offices of the Society, 26, Budge-row, or from Mr. George Offer, 4, Great Winchester-street.

Electric Traction in Vienna.—The Anglo-Bank, which took up 10,000 Preference shares in the Neue Wiener Tramway Gesellschaft have made an offer to the Board of that company to introduce electric traction on some of their lines. If their proposal is accepted the work will be carried out by the Allgemeine Electricitäts Gesellschaft, and the cars run at a fixed price per car kilometre.

Commissioners of Sewers.—Among the petitions presented for signature to the Commissioners of Sewers by the Finance and Improvement Committee at their last meeting was one against the Central London Railway Bill, one against the London Subways and Overhead Wires Bill, and one against the City of London Electric Lighting Bill. The petitions were read to the Court with closed doors.

Incandescent Lamp Signalling.—At the beginning of the present month the American squadron, while lying in Toulon roads, engaged in some striking signalling experiments with incandescent lamps placed on the yards. The experiments were completely successful, the signals from the flagship "Chicago" being easily and quickly interpreted and responded to by the three other ships of the squadron.

Cologne.—From the *Electrotechnisches Echo* we learn that at the meeting of the Town Council on January 25th, Dr. Hegener, of the Municipal Gas and Waterworks, reported on the eight lighting schemes submitted and declared in favour of alternating currents. The proposed station will be in the centre of the town, and will have a capacity of 5,000 incandescent lamps. A credit for 1,850,000 marks was ultimately granted.

Bridlington Quay.—A public meeting of the ratepayers was held on Friday evening last for the purpose of considering the position of affairs with regard to public lighting. Dr. Redman moved "that in the opinion of this meeting the immediate adoption of electricity for public lighting purposes would be a very great improvement, and of great advantage to the ratepayers at large." The resolution was declared carried amidst loud applause.

Country House Lighting.—Mr. W. R. Cookson is having the electric light fitted to Binfield Park, Bracknell. There will be in all over 200 lights, and current will be supplied by a "Parsons" dynamo and accumulators. The generating plant will be situated at the stables and connected to the house by underground conductors, insulated on the "Brooks" oil system. Mr. A. A. Campbell Swinton has been entrusted with the contract for the installation.

An Alternate-Current Electric Clock.—The Helios Company of Frankfort-on-Maine have recently exhibited an alternating-current clock. From measurements taken by the *Electrotechnische Zeitschrift*, the clock takes about ·06 amperes and 34 volts, which, assuming even that there is no self-induction, is only two watts. A number of such clocks would drive synchronously off quite a small motor, and would, of course, keep absolutely together.

Heilbronn.—The Cement Company at Lauffen-on-the-Neckar, which possesses superfluous water power to the extent of 800 horse-power, has obtained permission to lay down a cable for the distribution of light and power in the town of Heilbronn. It is anticipated that 700 horse-power will be available for distribution. The public lighting at present consists of 480 lamps and costs 18,360 marks per annum, and the Town Council have agreed to replace the 480 gas lamps by 120 arcs.

The Liverpool Overhead Railway.—Rapid progress is being made with this railway. At present the work is being pushed forward from the north end of the city, and it is intended to work from the south or Garston end as well, without delay. The contractor hopes to have the whole line completed by July, 1891. No decision as to the system to be adopted will be come to until the last possible moment, in order that the latest developments and improvements in electricity may be taken advantage of.

Magnetic Storms.—In a recent note in the *Comptes Rendus*, M. Zenger remarks:—"I have compared the days of magnetic storms and of aurora borealis with the days of the solar period of 12·6 days, and with the days of the periodic passages of meteoric swarms. The almost absolute coincidence of the dates leads to the conclusion that the electric phenomena produced by the solar influence and by the direct electric discharge between the meteoric swarms and the upper regions of the earth's atmosphere are the cosmic causes which produce both magnetic storms and the aurora."

Extension of the Telegraph Money Order System.—On and after the 1st of March next the Post Office will extend this system, so that money may be transmitted by Telegraph Money Order between all head and branch offices in the United Kingdom at which Telegraph and Money Order business is transacted. In addition to the minimum commission of 4d., a charge will be made at the ordinary Inland rate for the

Digitized by Google

official telegram authorising payment at the Office of Payment and for the repetition thereof, the minimum being 9d.

A Correction.—Physical Society.—In the table of numbers inserted in our report of the discussion of the Paper on "Galvanometers," and published on page 370 of our last issue, the number 4,000 in column D should be 40,000, and in column V the last two numbers should be 125 instead of 250. This mistake also affects the numbers given in the last two columns. Lower down, after the words "Messrs. Elliott's usual practice," the words "many years ago" should have been added. The galvanometer here referred to was No. 1, not No. 3 as stated.

Killarney.—An interesting illustration of the utilisation of natural forces for electric lighting, says the *Freeman's Journal*, is about to be carried out in the town of Killarney. The current for lighting the town is to be generated by water-power at the Flesk Mills, situated a mile and three-quarters from the town, where there are two large water-wheels, which will give ample power in summer and winter for the purpose. Current for some 2,000 lights will be carried overhead on high poles. It is expected that the hotels and all the principal buildings in the town will take the light.

International Exhibition of Mining and Metallurgy.—An exhibition bearing this title will be held on an extensive scale at the Crystal Palace from July 2nd to September 30th next. The exhibition will comprise various kinds of machinery in motion and at rest; mining and treatment of all kinds of metals; electricity in its application to mining and metallurgy, electrical haulage, the electric lighting of mines, electric transmission of power, electrical extraction, processes, telpherage, &c. Further information may be obtained at the offices, 18, Finch-lane, E.C., and applications for space must be forwarded not later than March 15th.

Electrical Competitions.—At its annual meeting in December the Société Industrielle d'Amiens decided to offer the following medals for competitions during 1890:—A gold medal will be given to the best shop or factory electric light installation which has been in operation for at least one year. The installation must be cheaper than gas; gas made on the premises for a 300 or 500 light installation being taken as a standard of comparison. Another gold medal will be awarded to some useful chemical application of electricity within the Amiens district. Finally, a gold medal will be awarded to any meritorious physical memoir.

Budapest.—It is intended to light the whole town by electricity, and the Mayor has asked the gasworks for an estimate. The gasworks offered to reduce the price of gas, and estimated the cost of electricity at 1·35d. per 100 watt-hour, equivalent to about £10 per annum for a 14 candle-power incandescent lamp, the cost of a 14 candle-power gas lamp being £4. In spite of this enormous difference, the town is negotiating for the introduction of the electric light, and will give the gas company till December (when their contract expires) to erect a central station. If this is not done the contract will be put into other hands, as it has been definitely decided to adopt the electric light.

Royal Meteorological Society.—At the last meeting of this Society Mr. E. S. Bruce read a note on "An Optical Feature of the Lightning Flash." It has been stated, he said, in the report of the Thunderstorm Committee of the Royal Meteorological Society that there is not the slightest evidence in the photographs of lightning flashes of the angular zigzag or forked forms commonly seen in pictures. The author, however, believes that this is an optical reality, as the clouds on which the projection of the flash is cast are often of the cumulus type, which afford an angular surface. In support of this theory he exhibited some lantern slides of lightning playing over clouds.

St. James's Vestry.—At the last meeting of this vestry in was agreed to petition against the Central London Railway Bill unless the promoters agreed to the insertion of a clause requiring the company to pay to the London County Council a substantial sum for improvements in consideration of their being allowed to construct the railway under the public thoroughfares. The Sanitary and Parliamentary Bills Committee submitted a report recommending the vestry to petition against the London Subways and Overhead Wires Bill of the London County Council, with a view to the insertion of clauses for the removal of overhead wires within some period to be specified by the Bill. This was carried.

The Puluj Telethermometer.—This telethermometer, which is due to Dr. J. Puluj, of Prague, consists of a carbon and iron spiral placed within a glass tube filled with hydrogen. The carbon and the iron form part of a Wheatstone bridge. Any variation of temperature causes their resistance to alter in opposite ways and thus upset the balance. The amount of this variation is determined by the amount of adjustment required to restore the balance. Variations of temperature of only ·1°C. taking place a kilometre distant can be easily detected by the instrument. Dr. Puluj, in a paper read before the Vienna Scientific Society, gives in detail the method of constructing a scale for the instrument graduated in degrees.

Carrara.—By July next M. Garré, of Carrara, hopes to be in a position to undertake the private and public lighting of the town, as well as the electric distribution of power. At the present moment two 120 horse-power turbines are in course of erection at a waterfall about a kilometre from the town, where a supply is available equal to 27 gallons per minute at a head of 260ft. M. Garré is negotiating with the authorities to light the town by means of 350 16 candle-power incandescents and 25 arcs, at 20 per cent. less than the gas company, and intimates his willingness to supply private customers at the rate of 35fr. per 16 candle-power lamp per annum. It is moreover estimated that 80 kilowatts will be available for power purposes.

The McLaughlin Storage Battery.—Several long trips have recently been made over the Philadelphia People's Line by a car equipped with 92 cells of the McLaughlin storage battery, 46 cells on each side of the car, and two 15 horse-power Sprague motors. With but one exception every trip of this car was satisfactory. The 92 cells were not all used at the same time while the car was in action; only half the number being operated for two hours at a time. The McLaughlin battery cell is 6in. square at the base, and 7in. high, and is composed of silica and sulphur. The plates consist of an alloy of tin and lead. The plate will, it is said, withstand a heavy rate of charge and discharge, and when formation is complete the metallic part of the plate becomes a part of and just as porous as the active material itself.

Berlin.—The following table shows the development of the Berlin Central Station:—

Station.	Effective Horse-Power.						
	1884	1885	1886	1887	1888	1889	When completed.
Friederickstrasse ...	300	300	300	300	300	300	300
Markgrafenstrasse ...	...	1,000	1,000	1,000	2,400	2,400	3,100

Edinburgh Exhibition.—A meeting of the London Committee of the Edinburgh Exhibition was held on Monday at the Mansion House. The chairman, Sir George Hayter Chubb, stated that he had recently visited Edinburgh in order to obtain information as to the progress of the Exhibition. The site was undeniably a good one. The space had been applied for twice over, and nearly 100 of the chief electrical firms would exhibit. Several sections would be reserved for foreign countries, some of whom were exhibiting officially. The guarantee fund amounted to £25,410, and though there was every reason to suppose that the Exhibition, like those held in Edinburgh and Glasgow of recent years, would result in a surplus, yet it was desirable that the guarantee fund should amount to £40,000. Various guarantees were handed in, and the committee separated.

Digitized by Google

London County Council.—At the last meeting of the Council the Highways Committee recommended :—"(*a*) That a petition be presented against the City of London Electric Lighting Bill, with a view to obtaining amendments; (*b*) That petitions be presented against the preamble of the Strand Electric Lighting Bill; (*c*) That a petition be presented against the preamble of the St. Martin-in-the-Fields Electric Lighting Bill." The recommendations were adopted. The Highways Committee also reported that they had proceeded upon the resolutions of the Council of December 3rd last as to certain appointments in the engineer's department, and they recommended that Mr. W. Arnot should be appointed, at a salary of £200 a year, to discharge the duties of an inspector under the Electric Lighting Acts, and other duties; that Mr. A. Champion be appointed, at a salary of £3. 3s. a week, to supervise the works; and that Mr. J. Somers be appointed in the engineer's department at a salary of £2 per week. This was approved.

Metropolitan Electric Lighting Areas.—We have received from Mr. Stanford, of Charing Cross, a large coloured map of London, on a scale of 3 inches to the mile, showing the Metropolitan areas allotted under the various Provisional Orders and Licences to supply companies and to the St. Pancras Vestry. The map, which is very similar to that issued as a supplement to *The Electrician* of January 3rd, should prove of great use to all concerned in the electric lighting of the metropolis. Its value would, we think, however, be considerably enhanced if the sites of the central stations of the different companies were prominently marked. The parish of Fulham is, we notice, marked as having been allotted under the Fulham District Order, which was, if we remember rightly, obtained in 1884 by the West Middlesex Electric Lighting Company, whose powers have now lapsed. We have also received from the Kensington and Knightsbridge Electric Lighting Company a map showing the houses in their district now fronting the Company's mains. The Company appear, from this map, to have practically covered the district.

Electrical Installation Rules.—We have received a copy of some rules for electric light installations, compiled and adopted by the Victorian Institute of Engineers and the Fire Underwriters' Association of Victoria. These rules have for the most part been taken without acknowledgment and with remarkable impartiality from those issued by the Institution of Electrical Engineers and by the Phœnix Fire Office. The maximum current which any conductor may carry is fixed by the formula $C = \sqrt{\frac{D}{R}}$; where R represents the resistance of 600ft. of the conductor at 120°F., and D is its diameter in mils. This formula results for small conductors in current density greater than the Board of Trade limit of 1,000 amperes per square inch, while for large conductors the current densities are considerably less. Acid, neutralised before being used, is allowed as a soldering flux. With a view, perhaps, of ensuring good insulation, both the Institution rule and Mr. Heaphy's (with some modifications) have been adopted. A table, giving the safe currents for stranded conductors, calculated from the formula mentioned above, is printed at the end of the rules.

A Second New Zealand Cable.—Our readers will probably remember that in consequence of the interruption for some twelve days last year of telegraphic communication between Australia and New Zealand, the Eastern Extension Telegraph Company decided to lose no time in duplicating their Sydney-Nelson cable, so as to prevent as far as possible further inconvenience to the telegraphing public. The manufacture of the duplicate cable is now completed, and it has been coiled on board the Telegraph Construction and Maintenance Company's s.s. "Scotia," which vessel left yesterday, 20th inst., for Sydney to lay the same. The new line is being put down solely to strengthen the service, the existing cable being fully equal to present traffic requirements. It may also be interesting to learn that the Telegraph Construction and Maintenance Company are manufacturing for the Eastern Extension Company 650 miles of cable for the partial renewal of their Madras-Penang section between Penang and a point west of the Nicobar Islands, where most of the interruptions to this cable have hitherto occurred. The carrying capacity of the new cable will be considerably greater than that of the existing line, and it is expected that this renewal will be carried out during the next few months.

The Overhead Wires at Glasgow.—At the meeting of the Town Council on Monday, the minutes of the Special Committee on overhead electric light cables and wires stated that at a meeting of the Committee on February 7th the clerk submitted correspondence with the Board of Trade and with Messrs. Muir, Mavor, and Coulson (Limited) in regard to overhead electric wires in the city. On behalf of the Board of Trade, Major Cardew, R.E., electrical adviser of the Department, had inspected the installation belonging to Messrs. Muir, Mavor, and Coulson (Limited). His report contained the following :—"This is one of the best installations I have yet seen. The insulated wire used is well up to the standard of our regulations, which have been generally complied with, except in a few cases." Mr. Gray, in moving the approval of the minute, said that although the city architect, Firemaster Paterson, and Mr. Cook, the electrical expert of the Corporation, did not quite agree with Major Cardew's report as to the danger arising from the wires, the Committee were of opinion that they had discharged their duty by calling attention to the matter. He thought, however, it might be better that the Committee should be continued, in order that such questions might be considered. The minute was adopted and the Committee was continued.

Telephone Promotion.—Mr. D. Sinclair, who has been for the last seven years or so engineer to the National Telephone Company in the Glasgow district and over the West of Scotland generally, has been promoted to the Metropolitan district of the same company. He will have entire charge of the four divisions embraced in the Metropolitan district. Prior to joining the telephone service in Glasgow, Mr. Sinclair was for some three or four years in the telegraph service of Japan, and previously he was a telegraph engineer in the employment of the North British Railway Company. As a skilled electrician he has taken high rank. During the last few years Mr. Sinclair read three valuable Papers on telephone matters before the Philosophical Society of Glasgow, and he latterly served on the Council of that Society. Before leaving for London he was presented with a handsome gold watch by the Glasgow staff of the National Telephone Company, as a token of the esteem with which they regarded him, and he was subsequently entertained to dinner by the male members of the staff. Mr. D. Johnstone Smith, C.A., local secretary to the Telephone Company, presided at both farewell meetings. Mr. Sinclair has left behind him many personal and professional friends in Glasgow and throughout the West of Scotland.

The Lighting of the City.—At the last meeting of the Commissioners of Sewers the Streets Committee brought up a report relative to the proposed contract with the Brush Electrical Engineering Company. The company proposes, among other things :—1. That the option of renewing the contract for public lighting after the first 21 years for successive periods of seven years shall be mutual. 2. That the power of the Commission to purchase at the end of 21 years, or at each succeeding seven years, be limited to public lighting only. 3. That the receipts and expenditure in respect of the contract be debited with 5 per cent. interest on the capital and a reasonable sum per annum for depreciation prior to arriving at the cumulative dividend of 10 per cent., and the application of the sliding scale as regards charges and profits. They also think the contract must be conditional on their obtaining a Provisional Order giving them the necessary Parliamentary powers over the district in question, and on their being able to obtain on reasonable terms all necessary way leaves and powers to enable them to lay their mains outside the district to the points at which the main conductors may enter the district, and they suggest that the contract be executed, with a supplemental contract of the same date, making it conditional, as above stated, and providing that the required deposit of £1,000 be returned to them in case these powers cannot be obtained. The Committee recommended the Court to resist Nos. 2 and 3, and to agree to the rest. The report was adopted.

MAGNETISM IN IRON AND OTHER METALS.*—VI.

BY PROF. J. A. EWING, F.R.S.

(*Continued from page 342.*)

§ 37.—**Methods of Measuring Magnetic Quality.**—From what has been said about the influence which the ends of magnetised bodies exercise in reacting on the magnetising field, and in exerting a self-demagnetising force when the external force is withdrawn, it will be clear that when we attempt to measure the permeability, or the susceptibility, or the retentiveness of a magnetic metal, we must either arrange the conditions of the experiment in such a way that the influence of the ends may be calculated and allowed for, or else choose pieces which are actually or practically *endless*.

We may use long ellipsoids (short ones will not do, for the reason already explained—that in them the magnetisation depends too much on the form and too little on the quality of the piece), and, having observed I, calculate the true magnetic force within the metal by subtracting N I from the externally applied force H'.

Again, if the piece tested is a very long cylindrical rod or wire, the influence of the ends may be approximately allowed for by treating the piece as an ellipsoid. And by making the length great enough (400 times the diameter or so if the rod is straight) we may reduce the influence of the ends so much that it may generally be neglected. In a rod long enough to be practically endless, the magnetic force within the metal is sensibly the same as the force in the field when the rod is withdrawn from it.

The condition of endlessness can be completely secured by giving the piece to be magnetised the form of a ring. If we take a ring of uniform section, and wind the magnetising coil uniformly all round it, we secure a magnetic field which is uniform throughout the length of the ring, and nearly uniform throughout each cross-section. The magnetic force operative on the metal is quite independent of the magnetism of the piece itself. The ring has no poles; it produces no reaction on the magnetising field; and when the external force is withdrawn it exerts no demagnetising force upon itself.

Ellipsoids, long rods, and rings have all been used in testing the permeability and other magnetic qualities of iron. Recent experiments have, as a rule, been made either with rings (or pieces equivalent to rings), or with very long cylindrical rods. From some points of view, long ellipsoids would be the most satisfactory of all forms of specimen, but the difficulty of shaping them correctly is a serious obstacle to their use.

§ 38. **Classification of Methods: Magnetometric and Ballistic.**—The magnetisation produced in a specimen by applying magnetic force, or, more generally, the change of magnetism produced by any change in the force, is usually measured in one or other of two ways.

In one—the magnetometric method—the magnetism of the piece is measured by observing the deflection of a magnetic needle suspended near it, called a magnetometer. This method is applicable when we deal with ellipsoids and rods, but obviously cannot be used with rings, since a uniformly magnetised ring exerts no magnetic force in the neighbouring space.

In the other method, any change in the magnetic induction within the specimen is determined by measuring the transient current which is induced in a surrounding coil when the change of induction takes place. The coil acts like the secondary wire of an induction coil or transformer. When any change takes place in the number of lines of induction surrounded by the coil, a transient current is produced, the whole quantity of which (that is to say, its time integral) is proportional to the change. This transient current is measured by passing it through a "ballistic" galvanometer, which is a galvanometer with a needle that swings slowly enough to allow practically the whole of the transient current to pass before the needle has stirred to any sensible extent from its position of rest. This "ballistic" method is applicable to rings as well as to rods of any form, and is in fact the only method by which we may examine the magnetic quality of a ring. When applied to rings it serves to measure sudden changes of magnetism only, such as may be caused by making, breaking, reversing, or suddenly increasing or reducing the current in the magnetising coil. When applied to rods the ballistic method may be modified, so that it will measure the actual magnetic state of the piece, and not sudden changes merely. This is done by winding the secondary coil so that it may be suddenly slipped off the magnetised piece, and removed far enough from it to be out of the reach of magnetic influence, remaining, however, all the while in circuit with the ballistic galvanometer. Slipping off the coil gives a transient current which corresponds to the sudden removal of all the lines of induction.

We shall now describe the two methods in some detail, and give examples of their application.

§ 39. **Magnetometric Method.**—In this method the rod or other piece whose magnetisation is to be measured is fixed near

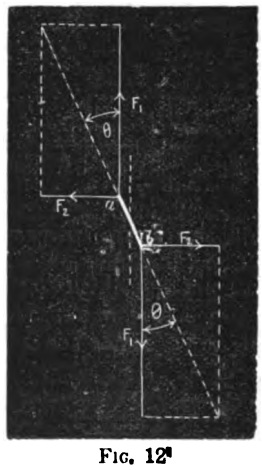

FIG. 12.

the magnetometer, the needle of which is already directed by some known magnetic force. Generally, the needle hangs horizontally under the control of the earth's magnetism alone, so that the directing force is the horizontal component of the earth's magnetic field. The magnetised piece is fixed in such a position that the magnetic force which it produces at the magnetometer, or what we may call the deflecting force, acts at right angles to the directing force. The tangent of the angle of deflection then measures the proportion of the deflecting to the directing force. Thus, in Fig. 12, if the magnetised

FIG. 13.

body is placed so that it produces a magnetic force F_2 at the magnetometer needle $a\,b$, and the directing force is F_1, the needle, which originally pointed in the direction of F_1, is deflected through an angle θ such that

$$F_2 = F_1 \tan \theta.$$

Knowing F_1 and observing θ, we determine F_2, and from that, knowing the position and dimensions of the magnetised piece, we calculate its intensity of magnetisation.

Suppose, for instance, that the magnetic bar is an ellipsoid of revolution (with polar axis $2c$ and equatorial axes $2a$) placed in

* All rights are reserved.

Digitized by Google

the position shown by the line C C′ in Fig. 13. The bar lies horizontally, level with the magnetometer needle O, which is opposite the middle of the bar and points to it when in the undeflected position. In its action on a distant point the ellipsoidal bar is, as we have seen in § 27, equivalent to a positive pole of strength $\pi a^2 I$ at Q and an equal negative pole at Q′, the distance Q Q′ being $\frac{4}{3}c$. The deflecting force F_2 which the bar produces at the magnetometer is the resultant of the equal forces

$$\frac{\pi a^2 I}{\overline{O Q}^2} \text{ and } -\frac{\pi a^2 I}{\overline{O Q'}^2}.$$

Its direction is parallel to the bar, and, as the diagram shows,

$$F_2 : \frac{\pi a^2 I}{\overline{O Q}^2} :: \overline{Q Q'} : \overline{O Q},$$

or

$$F_2 = \frac{\pi a^2 I \overline{Q Q'}}{\overline{O Q}^3} = \frac{4 \pi a^2 c I}{3 \overline{O Q}^3}.$$

And, since $F_2 = F_1 \tan \theta$, we may put this result in the following form, suitable for finding the intensity of the bar's magnetisation :—

$$I = \frac{3 \overline{O Q}^3 F_1 \tan \theta}{4 \pi a^2 c}.$$

(To be continued.)

UNDERGROUND MAINS.

BY G. L. ADDENBROOKE.

VI.

(Concluded from page 369.)

THE CALLENDER BITUMEN COMPANY'S SYSTEMS.

In a quiet and steady manner this company, whose experience of underground mains is second to none, have been taking a large share in the underground-main laying which has lately been done. They have worked out two or three complete systems to suit different purposes, besides the manufacture of their bitumen-covered cables.

From the commencement of electric lighting the Callender Company has identified itself with underground work, and they had considerable experience first of all in laying mains for large private installations. The method of construction they have chiefly used for this work consists, in the first place, of a ¾in. wooden trough, having only a bottom and two sides; across the bottom of this trough wooden bridge-pieces are laid every two feet or so, having two or three notches as required to take the cables. These bridge-pieces merely serve to keep the cables from touching the bottom of the trough. After the cables have been laid, the whole trough is filled with bitumen to the top, thus embedding the cables in a thick, impervious coating of highly insulating material. After a time the bitumen sets, so that it is not a matter of the first importance whether the wood remains sound or not, as the bitumen will still retain its form. It is found also that it is sufficiently elastic to follow any slight subsidence of the ground without cracking. The company state that they have many private installations in which this method of laying the mains has been followed, and which have been running since 1883 without giving any trouble.

For central station work the company uses generally a more elaborate system, but of the same type as the above; three sided iron troughs—that is, with a bottom and two sides—being substituted for the wooden ones, as shown in Fig. 19. These iron troughs are made in 6ft. lengths, and have overlapping joint, and succeeding lengths are held together by a screw and bolt just to keep them in their places; there is considerable play in these joints, so that the troughs can be made to follow curves, though a curved pattern is used when the bends are very sharp. These troughs, when laid, are fitted with the wooden bridge-pieces already described, and the cables laid each in its notch; the trough is then filled with bitumen, and a thin layer of concrete put over the top, or the top may have an iron covering. The troughs are made to contain two, three, or four cables, as required, and two layers of cables can if necessary be put in one above the other. As far as possible the company avoid joints in continuous lengths of cable, but where they are necessary the inner layers are scarf-jointed, and the outside married together, and the joint is run solid with solder. Insulating material is then lapped round the joint to the full thickness of the insulation of the cable. This lapping material is only half vulcanised when it is put on; a lamp is brought underneath afterwards, and the whole warmed so as to complete the vulcanisation and make all the lapping solid.

The principle on which the company advise laying mains is as far as possible to complete the service mains in each locality to their full probable ultimate capacity at once, their experience being that, taking into consideration the cost of getting up the streets and making good again, besides troughs, &c., the extra amount of cable required to complete the service mains does not form a very large additional expense as compared with the others, and when once the work is carried out and completed there is no further outlay. It is not proposed that the full number of feeders should be put in at once; these can be added afterwards as required, and as the lights get taken up.

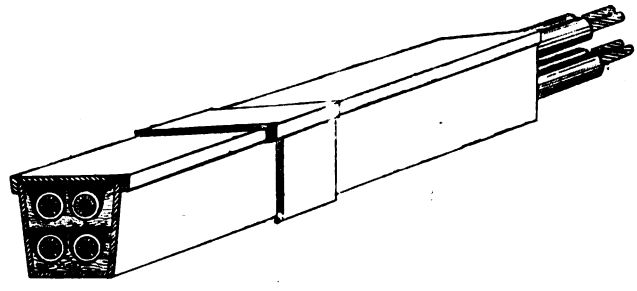

FIG. 19.—Callender Company's system. Iron trough for cables filled with bitumen.

The mains for the Liverpool Electric Lighting Company, whose career has been so successful, have been laid by the Callender Company on this principle, and a special class of junction-boxes has been devised to work with it. These junction-boxes are of cast iron and nearly square, and the cables are brought in at the two ends. The opposite ends of each of these cables are then united by bronze bridge-pieces, and from these bridge-pieces the connections are made for local customers. The system which has been pursued at Liverpool is to place one of these junction-boxes opposite the centre of each block of buildings, the various connections for the houses in that section of street radiating from this box, and being formed by laying lead-covered cables in wooden troughs filled with bitumen. One junction-box thus, as a rule, serves several houses, though in some cases when a large establishment takes a great number of lights a special junction-box is used for this one place alone. The cables connecting to customers come in at the side of the box, and are brought up to bronze connections, from whence they can be connected across to the mains, and cut-outs are usually inserted at the junctions. The box itself is partially filled with bitumen, so as to cover over all the cables and the joints where they enter the box, and this bitumen is made continuous with that in the troughs outside. Great pains are taken with the lids of these boxes, which, by means of a bolt through the middle, and an india-rubber packing all round the edge, are kept absolutely watertight. A separate lid of the G. P. O. type fits over the box-lid.

For heavy feeders the Callender Company have been laying at Liverpool large cables of 1,000 square millimetres section, thoroughly insulated with bitumen, and then covered with a lead tube of ample thickness. Two of these are laid in a deep narrow trough, one above the other, and the whole filled with bitumen. With such precautions there seems no reason why such work should not last indefinitely.

Digitized by Google

At Bath the "solid" system is being used for high-tension alternating-current and arc-lighting wires.

Besides the systems already described, the Callender Company, as is well known, also make conduits on the Callender-Webber system. This is a drawing-in-and-out system, with a separate hole for each cable. Messrs. Callender state that their experience of cables drawn into pipes several together is that, although it may be possible to add single cables when required, yet that the cables will overlay each other and get interlaced

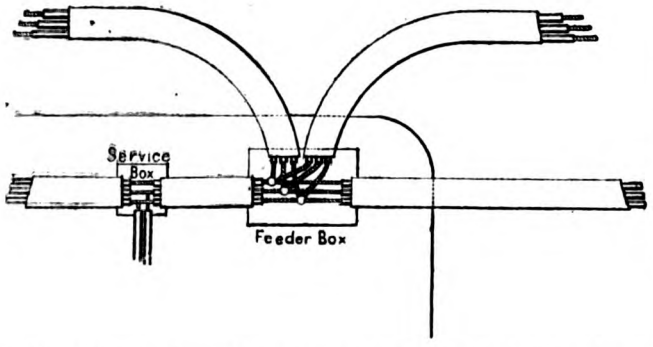

FIG. 20.—Callender Company's system. General method of running the mains and feeders (plan).

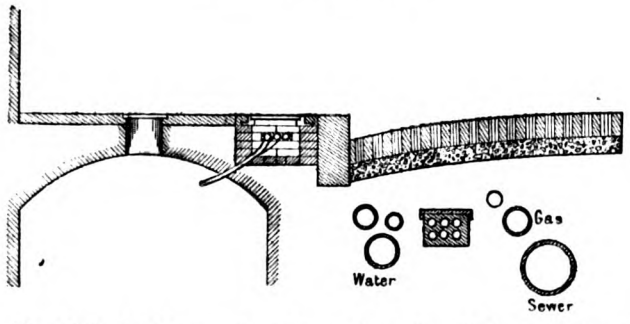

FIG. 21.—Callender Company's system. General method of running the mains and feeders (section).

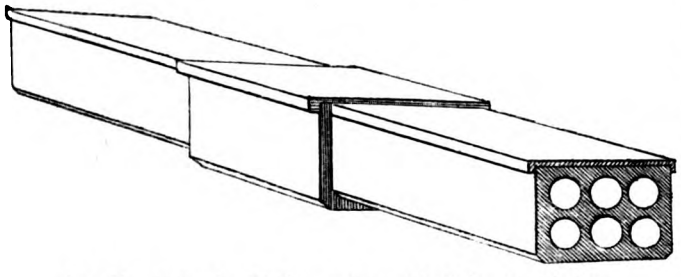

FIG. 22.—Callender-Webber system. Conduit, general view.

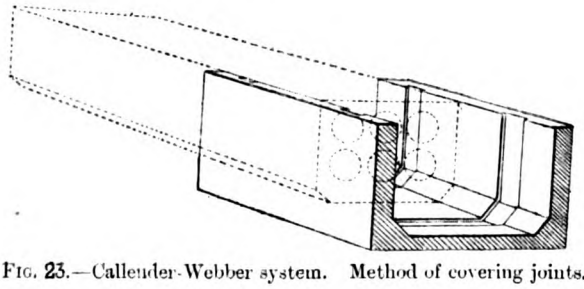

FIG. 23.—Callender-Webber system. Method of covering joints.

in such a way that it is very difficult to withdraw any one of them afterwards should it need repair. Figs. 20 and 21 show in plan and section the general method of running the feeders and mains. The feeders are usually carried under the roadway and the service mains under the footpaths.

There are various ways in which the conduits are formed, according to the purpose for which they are to be used and the size of the cables they will have to carry. In the form which the Chelsea Electric Light Company are using, the cases are laid plain, without further protection, but in the work which has been put down for Messrs. A. and S. Gatti in the Strand, the bitumen conduit is enclosed in a three-sided iron trough, which is used upside down; that is, there is iron above but none below where the conduit rests on the ground. Figs. 22 and 23 show the general form of the conduits, the method of protecting them, and of covering the joints. These bitumen conduits with the holes through them are made to project about a couple of inches at each end beyond their iron case. To join them together, two are brought end to end, and long mandrils of the proper size pushed through the holes into the next block so that they pass through the joints. Hot bitumen is then poured over the joint and the conduit pressed against its neighbour. A short piece of iron troughing of the same shape as the longer pieces containing the conduit is then made hot and slipped over the joint, melting the bitumen to some extent and making everything perfectly solid and water-tight. After the joint has had time to cool sufficiently, the mandrils are withdrawn, and the addition of the next section proceeded with. The Callender Company state that they are able to draw long lengths of cable into these conduits and to withdraw them if necessary.

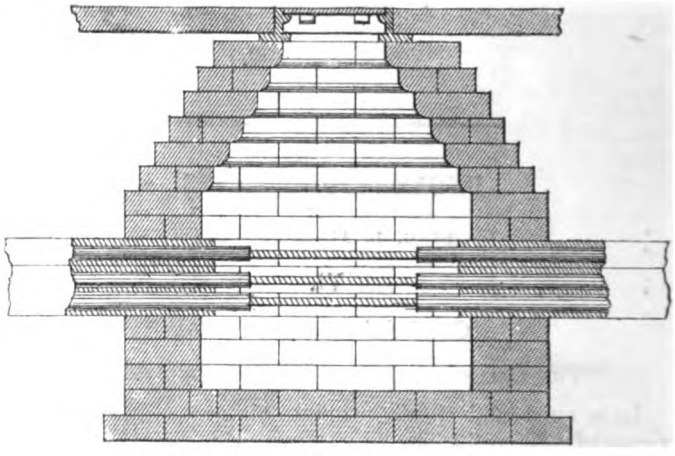

FIG. 24.—Callender-Webber system. Manhole.

Junction-boxes and manholes are used with this system as per sketch (Fig. 24), being arranged to suit the requirements of each special case.

It will be noticed that in joining together the sections in the Callender-Webber system the blocks are simply made continuous, nothing being used at the joints. This is a somewhat important point, as the paper tubes used to keep the holes free at the joints, in work somewhat on the same lines in America, have proved a considerable source of subsequent trouble. It has often been objected to this class of conduit that it may crack, but in practice it is not found to do so: the bitumen, being of a slightly viscous nature, has always a certain amount of give in it.

CONCLUSION.

The description of the leading systems of laying underground mains at present in use is now concluded, and a tabulated list is appended giving the methods and systems employed in many of the best-known installations, which in this form it is thought may prove useful, and to which the editor will be glad to receive any additions.

LIST OF CENTRAL ELECTRIC LIGHT STATIONS SHOWING CHARACTER OF UNDERGROUND DISTRIBUTING SYSTEM.

Town.	Company and System.	Underground Mains.
London	London Electric Supply Corporation; alternating, 2,400 volts.	India rubber cables in iron pipes. Siemens' concentric cable. Ferranti patent main.
"	Metropolitan Electric Supply Company; alternating, 1,000 volts.	Chiefly india rubber cables in iron pipes.
"	House-to-House Electric Light Supply Company; alternating, 2,000 volts.	India rubber cables in iron pipes.

Town.	Company and System.	Underground Mains.
London	Kensington and Knightsbridge Electric Lighting Company; low tension.	Cement conduits with bare copper rods on glass insulators. Callender cables when no room for this. (Crompton system.)
„	St. James and Pall Mall Electric Light Company; low tension.	Copper strips on china insulators in iron troughs.
„	Chelsea Electricity Supply Company; low tension and battery.	Callender-Webber conduits and Callender cables.
„	Gatti Bros., Strand; low tension.	Callender-Webber system.
„	Westminster Electric Supply Corporation; low tension.	Probably Crompton's system.
Bradford.....	Corporation; low tension.	Siemens' cables.
Leamington...	Midland Electric Light and Power Company; low tension.	Brick conduits and Callender cables.
Bath.....	Bath Electric Light Works; arc and alternate, 2,000 volts.	Callender, solid conduits.
Eastbourne... Hastings..... Brighton.....	Local Companies; alternating, 1,000 volts and arcs.	India rubber cables, in iron pipes when underground.
Liverpool	Liverpool Electric Supply Company; low tension.	Callender, solid bitumen conduits.
Paris	Municipality. Halles Centrales; alternating, low tension.	Rubber-covered cables on insulators in conduits and sewers.
Berlin	Low tension.	Siemens' armoured cables.
Rome ..... Milan ..... Turin	Alternating, 2,000 volts.	Siemens' armoured concentric cables.
New York ...	Edison Company; low-tension.	Edison Company's system and cables, in separate iron pipes for feeders.
New York ...	Illuminating Company; chiefly arc.	Board of Electrical Control subways, chiefly iron pipes and hard rubber lead-protected cables.
Chicago	Illuminating Company; chiefly arc.	Principally iron pipes with okonite cables in them, partly sewers.

PROBLEMS IN THE PHYSICS OF AN ELECTRIC LAMP.*

BY PROF. J. A. FLEMING, M.A., D.SC., M.R.I.

More than eighty years ago Sir Humphrey Davy provided the terminal wires of his great battery of 2,000 pairs of plates with rods of carbon, and, bringing their extremities in contact, obtained for the first time a brilliant display of the electric arc.† The years that have fled away since that time have seen all the marvellous developments of electro-magnetic engineering, have placed in our possession the electric glow-lamp, and brought the art of electrical illumination to a condition in which it progresses each year with giant strides. In addition to the importance attaching to their ever-increasing industrial use, there are many questions of purely scientific interest which present themselves to our minds when we proceed to examine the actions that take place when a carbon conductor is rendered incandescent in a high vacuum, or when an electric arc is formed between two carbon poles. It is to a very few of these physical problems that I desire to direct your attention to-night, but more especially to one which is particularly interesting from the bearing which it has on the general nature of electric discharge.

We know as a very familiar fact that if we attempt to raise the temperature of a carbon conductor enclosed in a vacuum beyond a certain limit, not far removed from the melting point of platinum, the carbon begins to volatilise with great rapidity. If an electric glow-lamp has passed through its carbon more than a certain strength of current, the glass bulb speedily becomes darkened by a deposit of this volatilised carbon condensed upon it; and experience shows us that we cannot raise the temperature of that carbon beyond a definite point without causing this waste of the conductor to become very rapid. In the highly rarefied atmosphere within the bulb of a glow-lamp, the carbon, when at its normal incandescence, must be considered to be projecting off molecules of carbon in all directions, partly in virtue of purely thermal actions, but probably also in consequence of certain electrical effects to be presently discussed. This scattering of the material of the carbon conductor takes place with disadvantageous rapidity from an industrial point of view at and beyond a certain temperature,* but it exists as well at much lower temperatures than that which is found to determine the practical limit of durability. A curious appearance is found in many incandescent lamps which have been "over-run," which shows us that this projection of carbon molecules from the hot conductor is not, perhaps, best described by calling it a vaporisation of its substance, but that the surface molecules are shot off in straight lines, and that they reach the glass envelope without being hindered to any great extent by the molecules of the residual air.

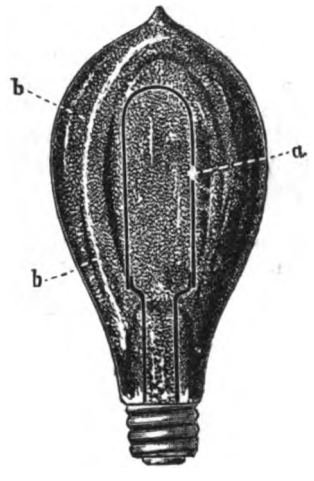

FIG. 1.—Glow lamp having the glass bulb blackened by deposit of carbon. Molecular scattering having taken place at *a*, and shadow or line of no deposit produced at *b*.

If an electric current is passed through an otherwise uniform carbon conductor, which possesses at any one place a specific resistance higher than that of the remaining portion, the current, in accordance with a well-known law, there develops a higher temperature, and the molecular scattering at that spot may in consequence be greatly exaggerated. It may be that the detrition of the conductor at that locality will be so great as to cut it through after a very short time. When the carbon has the form of a simple horseshoe loop, and when this molecular scattering takes place from some point in the middle of one branch, the molecular projection makes itself evident by producing a "molecular shadow" of the other leg upon the interior of the glass. I will project upon the screen an image of the carbon horseshoe loop taken from an old glow-lamp, and you will be able to see that the filament has been cut through at one place. At that position some minute congenital defect caused the carbon to have a higher resistance, the temperature at that point when it was in use became excessive, and an intensified molecular scattering took place from that locality. On examining the glass bulb from which it was taken, we find that the glass has been everywhere darkened by a deposit of the scattered carbon except along one narrow line, (*see* Fig. 1), and that line is in the plane of the carbon loop and on the side opposite to the point of rupture of the filament.

* A discourse delivered at the Royal Institution on Friday evening, February 14, 1890.

† Sir Humphrey Davy laid a request before the managers of the Royal Institution on July 11, 1808, that they would set on foot a subscription for the purchase of a large galvanic battery. The result of this suggestion was that a galvanic battery of 2,000 pairs of copper and zinc plates were set up in the Royal Institution, and one of the earliest experiments performed with it was the production of the electric arc between carbon poles, on a large scale. It is probable, however, that Davy had produced the light on a small scale some six years before, and, according to Quetelet Curtet, observed the arc between carbon points in 1802. *See* Dr. Paris' "Life of Sir H. Davy."

* When the rate of expenditure of energy in the carbon conductor is raised until it reaches a value of about 500 watts, or 360 foot-pounds per second per square inch of radiative surface, a limit of useful temperature has been reached for economical working, under the usual present conditions of steam-engine-driven dynamos and modern glow-lamps.

Digitized by Google

I might illustrate to you by a very simple experiment the way in which that "shadow" has been formed. Here is a ∩-shaped rod: this shall represent the carbon conductor in the lamp; this sheet of cardboard placed behind it, the side of the glass receiver. I have affixed a little spray-producer to one side of the loop, and from that point blow out a spray of inky water. Consider the ink spray to represent the carbon atoms shot off from the overheated spot. We see that the cardboard is bespattered on all points except along one line where it is sheltered by the opposite side of the loop. We have thus produced a "spray shadow" on the board (Fig. 2). The existence of these molecular shadows in incandescent lamps leads us therefore to recognise that the carbon atoms must be shot off in straight lines, or else obviously no such sharp shadow could thus be formed. This phenomenon confirms in a very beautiful manner the deductions of the Kinetic theory of gases. I may remind you that at the ordinary temperature and pressure the mean free path of a molecule of air is deduced to be about four one-millionths of an inch. This is the average distance which such a gaseous molecule moves over before meeting with a collision against a neighbour which changes the direction of its path. Let the air be rarefied, as in these bulbs, to something like a millionth of the ordinary atmospheric pressure, and the mean free path is increased to several inches. The space within the bulb—though from one point of view densely populated with molecules of residual air—is yet, as a fact, in such a condition of rarefaction that a carbon molecule projected from the conductor can move over a distance of three or four inches on an average without meeting with interference by collision with another molecule, and the facts revealed to us by these shadows show that this must be the case. I have also at hand some Edison lamps in which these "molecular shadows" are finely shown, but in these cases the deposit on the interior of the bulb is not carbon but copper, because the molecular scattering has here taken place by excessive temperature developed at the copper clamps by which the carbon filament is attached to the platinum wires.

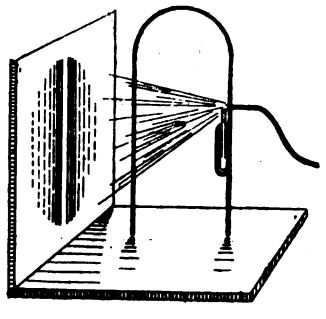

Fig. 2.—"Spray shadow" of a rod thrown on blotting paper screen to illustrate formation of molecular shadow in glow lamps.

The theory, however, is the same. The deposit of copper shows a fine green colour by transmitted light in the thinner portions. One curious lamp also before me had by an accident an aluminium plate volatilised within the bulb. The glass receiver has in consequence been covered with a mirror-like deposit of aluminium, which on the thinner portions shows a fine blue colour by transmitted light, and a silvery lustre by reflected light. This lamp also shows a fine "molecular shadow."

These facts prepare us to accept the view that when a glow-lamp is in operation the highly rarefied residual air in the interior of the bulb is being traversed in all directions by multitudinous carbon atoms projected off from the incandescent carbon conductor. I now wish to pass in review before you some facts which indicate that these carbon atoms carry with them electric charges, and that they are charged, if at all, with *negative electricity*. I may preface all by saying that much of what I have to show you will be seen to be closely related to the phenomena studied by Mr. Crookes in his splendid and classical researches on radiant matter. Our starting-point for this purpose is a discovery made by Mr. Edison in 1884, and which received careful examination at the hands of Mr. Preece in the following year,* and by myself more recently. Here is the initial experiment. A glow-lamp having the usual horseshoe-shaped carbon (*see* Fig. 3) has a metal plate held on a platinum wire sealed through the glass bulb. This plate is so fixed that it stands up between the two sides of the carbon arch without touching either of them. We shall illuminate the lamp by a continuous current of electricity, and for brevity's sake speak of

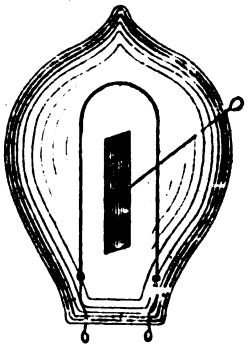

Fig. 3.—Glow lamp having insulated metal. Middle plate M sealed into bulb to exhibit "Edison effect."

that half of the loop of carbon on the side by which the current enters it as the negative leg, and the other half of the loop as the positive leg. The diagram in Fig. 4. shows the posi-

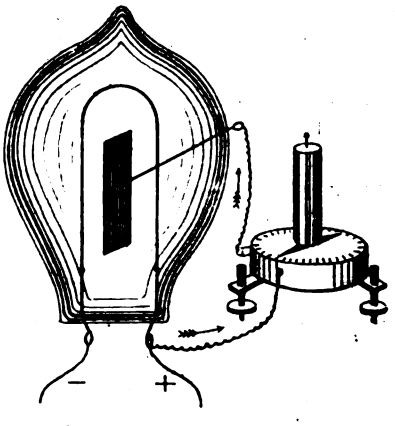

Fig. 4.—Sensitive galvanometer connected between the middle plate and positive electrode of a glow lamp, showing current flowing through it when the lamp is in action ("Edison effect").

tion of the plate with respect to the carbon loop. There is a distance of half-an-inch, or in some cases many inches, between either leg of the carbon and this middle plate. Setting the

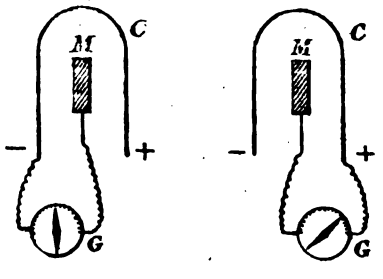

Fig. 5.—Mode of connection of galvanometer G to middle plate M and carbon horse-shoe shaped conductor C in the experiment of the "Edison effect."

lamp in action, I connect a sensitive galvanometer between the middle plate and the *negative terminal* of the lamp, and you see that there is no current passing through the instrument. If, however, I connect the terminals of my galvanometer to the middle plate and to the *positive electrode* of the lamp, we find a current of some milliamperes in passing through it. The diagrams in Fig. 5 show the mode of connection

* Mr. Preece's interesting Paper on this subject is published in the *Proceedings of the Royal Society* for 1885, p. 219. See also *The Electrician* April 4, 1885, p. 436.

Digitized by Google

of the galvanometer in the two cases. This effect, which is often spoken of as the "Edison effect," clearly indicates that an insulated plate so placed in the vacuum of a lamp in action is brought down to the same potential or electrical state as the negative electrode of the carbon loop. On examining the direction of the current through the galvanometer we find that it is equivalent to a flow of negative electricity taking place through it *from* the middle plate *to* the positive electrode of the lamp. A consideration of this fact shows us that there must be some way by which negative electricity gets across the vacuous space from the negative leg of the carbon to the metal plate, whilst at the same time a negative charge cannot pass from the metal plate across to the positive leg Before I pass away from this initial experiment, I should like to call your

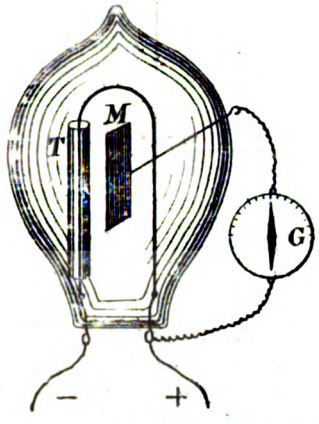

FIG. 6.—Glow lamp having negative leg of carbon enclosed in glass tube *T*, "Edison effect" thereby being annulled or greatly diminished.

attention to a curious effect at the moment when the lamp is extinguished. Connecting the galvanometer as at first, between the middle plate and the negative electrode of the lamp, we notice that though made highly sensitive the galvanometer indicates no current flowing through it whilst the lamp is in action. Switching off the current from the lamp produces, as you see, a violent kick or deflection of the galvanometer, indicating a sudden rush of current through it.

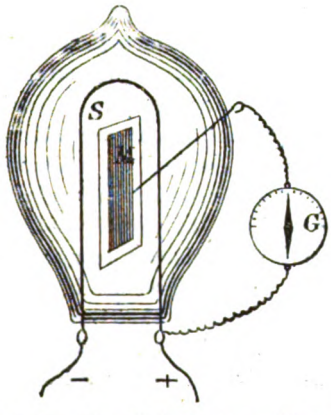

FIG. 7.—Glow lamp having mica shield *S* interposable between middle plate *M* and negative leg of carbon, thereby diminishing the "Edison effect."

In endeavouring to ascertain further facts about this effect one of the experiments which early suggested itself was one directed to determine the relative effects of different portions of the carbon conductor. Here is a lamp (*see* Fig. 6) in which one leg of the carbon horseshoe has been enclosed in a glass tube of the size of a quill, which shuts in one half of the carbon. The bulb contains, as before, an insulated middle plate. If we pass the actuating current through this lamp in such a direction that the covered or sheathed leg is the *positive* leg, we find the effect existing as before. A galvanometer connected between the plate and positive terminal of the lamp yields a strong current, whilst if connected between the negative terminal and the middle plate there is no current at all. Let us, however, reverse the current through the lamp so that the shielded or enclosed leg is now the negative one, and the galvanometer is able to detect no current, whether connected in one way or in the other. We establish, therefore, the conclusion that it is the negative leg of the carbon loop which is the active agent in the production of this "Edison effect," and that if it is enclosed in a tube of either glass or metal, no current is found flowing in a galvanometer connected between the positive terminal of the lamp and this middle collecting plate.

Another experiment which confirms this view is as follows:—This lamp (*see* Fig. 7) has a middle plate, which is provided with a little mica flap or shutter on one side of it. When the lamp is held upright the mica shield falls over and covers one side of the plate, but when it is held in a horizontal position the mica shield falls away from the front of the plate and exposes it. Using this lamp as before we find that when the positive leg of the carbon loop is opposite to the shielded face of the plate, we get the "Edison effect" as before in any position of the lamp. Reversing the lamp current and making that same leg the *negative* one, we find that when the lamp is so held the metal plate is shielded by the interposition of the mica, and the galvanometer current is very much less than when the shield is shaken on one side and the plate exposed fully to the negative leg.

(To be continued.)

HIGH AND LOW TENSION.

The controversy which was started exactly two years ago, at the Institution of Electrical Engineers, on the relative merits of transformer and accumulator methods of distribution, served a valuable purpose in revealing the various advantages which these rival systems possess, and, by stimulating competition, contributed much to advance electrical industry as a whole. It even caused some engineers to partially adopt the use of the system which they had previously very strongly opposed. It is, however, much to be regretted, in the interests of the electrical profession in general, that this controversy, which has never died out, and which has continually reappeared in some form or other, has lately taken a much less praiseworthy turn. The great energy and enterprise of the advocates of high-tension alternating systems in England and in America has, on the whole, been attended with striking success. The workers of low-tension systems declare, however, that the use of such high pressures is dangerous to life and should be stopped. Articles to this effect have appeared in the English and American press, but, as commercial interests have in many cases formed the chief motive for writing, the conclusions arrived at must be treated *cum grano salis*. The discussion originated with the overhead wire dispute in New York. This has aroused a great deal of interest on both sides of the Atlantic, and an excellent opportunity has thus arisen for calling attention to another matter with which it has little or no connection. The emphatic statement of Mr. EDISON, that "there is no plea which will

Digitized by Google

justify the use of high-tension or alternating currents," which, according to him, are dangerous, unreliable, and unsuitable for use, is too evidently biassed to be worthy of notice were it not for the fact that such statements, made by public men, are likely to bring about restrictive legislation, which there may be nothing to justify, and which would certainly injure electrical interests as a whole. It is to the interest of electrical engineers generally to encourage progress in every direction. The present condition of electrical industry is such, that advance in any one direction is a benefit to the whole profession. Everyone admits that the transmission of power to long distances is only possible by means of the employment of high electric pressures, so that the attempt to restrict the use of such high potentials will not only tend to seriously injure an important branch of electrical engineering, but will also prevent the natural development of another, which in the future will probably be of the greatest importance. The present acrimonious assertion of the defects of each system by the advocates of the other is also likely in many instances to dissuade the public from using either of them, whereas there is plenty of work for both.

Each system possesses many undisputed advantages, some of which we may briefly enumerate. A low-tension continuous-current system is very highly efficient and eminently suitable for thickly populated districts for comparatively short distances around the central station. Excellent motors can be obtained to work in connection with the system, which, moreover, possesses all the advantages of storage, viz., steadiness in action and the avoiding of continuous work, so that the engines can be always driven at full load. When electricity has to be supplied over larger areas the cost of the conductors may be diminished by the use of three-wire or other multiple conductor systems, and by arrangements of feeders. In spite of the extra complication thus introduced, the working is economical and satisfactory. The margin of profit, when gas is as cheap as it is in England, is so small in many cases, however, that the diminution in cost of the conductors obtained by the use of higher tensions is sufficient to make the difference between success and failure. At present this state of things in many cases renders a high-tension system the only remunerative one possible. With high-pressure systems it is possible for the central station to be placed at a distance from the area of supply, in a position where coal and water may be had cheaply, and where its presence will inconvenience none. With alternating currents it is possible to transform efficiently the high-pressure electricity necessarily used for economy, into low-pressure electricity suitable and safe for house-lighting. There is no question that for the lighting of scattered districts it is the only system which can pay, and that where overhead wires are permissible it is exceedingly economical. On the other hand, alternating-current motors are as yet not nearly so efficient as direct-current ones, and the economy effected in conductors is diminished if they have to be placed underground, since in that case the cost of the conductors is only a part of the cost of the circuit. There is no power of storage, and although this is not so necessary for steadiness when large amounts of power are being supplied, the absence of it necessitates the engines being run continuously whether the load is small or large.

The question of danger which has been raised in connection with high-tension systems may refer, either to the danger of fire caused by short-circuiting or to the danger to human life. The former is not seriously insisted on as important in carefully organised installations. The real point is whether the accidents which have happened in connection with high-tension systems are sufficiently numerous to justify the public in regarding them as dangerous. Our opinion is distinctly the reverse. Practically, all these accidents have occurred in America, where installations are managed in a much less careful way than in this country. It cannot justly be concluded from such experience that high potentials should be prohibited in England as dangerous, any more than the occurrence of serious railway accidents in America could justify the prohibition of high speeds on our own railways. Moreover the number of casualties in America, caused by the use of high potentials, is small compared with those due to street accidents about which no notice is taken. The objection of danger is always put forth to delay the progress of every improvement the ultimate success of which is assured. Even if all the accidents reported were true, and had occurred in this country, the logical conclusion would be, not to prohibit such high potentials, but to insist upon the need for greater precautions in laying the mains and in ensuring better insulation. Danger to life depends not so much upon the electrical potentials employed as upon the quality of the electrical contact with the mains; for, if this contact be sufficiently good, even the so-called low tensions may become highly dangerous. The employment of mains of the Ferranti or concentric type obviates any danger, since the outer tube differs in potential very little from the earth, and this remains true even if the insulation between the tubes breaks down. It is too early yet to pronounce any opinion upon the durability of the insulation intended for such high potentials as are about to be employed at Deptford. Only practical experience can decide. At the same time mains have been made to endure for years potentials of over 2,000 volts, and there is no reason to think that they cannot be made equally successful with the higher potentials proposed. The success of the Grosvenor Gallery installation and its remarkable freedom from accidents is sufficient witness to the possibility of success of systems employing tensions of over 2,000 volts. The clamour which has arisen with regard to the dangers accompanying high-potential distributions is not, therefore, justified by the facts connected with carefully organised work.

THE INSTITUTION OF ELECTRICAL ENGINEERS.

THE THEORY OF ARMATURE REACTIONS IN DYNAMOS AND MOTORS.*

BY JAMES SWINBURNE.

(Continued from page 375.)

REVERSAL OF THE SECTIONS UNDER THE BRUSHES.

As a convolution passes under a brush its current falls from the normal to zero, and then rises to the normal in the other direction, and the brush leaves the commutator strip just at that instant, else there would be sparking. To find what field the convolution must be passing through to produce this result, the variation of the number of lines of induction through the convolution must be found, and the time of short-circuiting known. Any lines of induction through the convolution must pass, 1st, round by the field magnets, thus taking the same course as the field-magnet induction; 2nd, through the armature and air gap in the same way as the field induction, and then from pole to pole across the external air like the field leakage; 3rd, through the iron of the armature in the immediate vicinity of the conductor, and round the conductor by the air (Fig. 5.) In a Gramme armature there are two more paths—4, like 3, only inside the armature ring, and 5, round the ring. The last is neutralised by the reversal of the opposite section, and if an uneven number of sections were used the closed armature circuit would damp it. As to the first, any variation of the induction of the field magnets would be damped by the closed copper field-magnet coils, not to speak of the closed armature coils forming the belt of back ampere-turns. In addition to this, if the current died away, and increased up to its normal in the opposite direction uniformly, the current-turns linked with the

* Read before the Institution on Thursday, February 13, 1890.

Digitized by Google

circuits 1 and 2 would remain constant, for on one side there is a constant increase of back current-turns, and on the other the reversed or forward turns are again crossing the lines 1 and 2. There could thus only be variation of induction round circuits 1 and 2 if the current in the section did not change uniformly. Any change in the induction round such a circuit as 2 would be damped by the Foucault currents produced in the pole-pieces, as the current is small and the frequency enormous.

The third course—3—may be treated as if the convolution were stretched out straight in air. The self-induction could then be calculated. As half the circuit round the wire is through iron, the self-induction may be doubled. The conductor may be taken as a linear conductor, and the self-induction of the active part taken within reasonable limits. To give some idea of the magnitudes dealt with, we may take, as an example, a drum armature of 15 cm. radius and 38 cm. length, with 120 external conductors, giving 100 volts and 400 amperes at 800 revolutions per minute. The self-induction of the active part may then be taken from 0·5 to, say, 5 cm. radius. Then

$$L = 38\int_{0\cdot5}^{5} \frac{4\,d\,r}{r} \times 10^{-9} = 350 \times 10^{-9}.$$

In a drum machine the neighbouring conductors belong to different convolutions, and in this case both are being commutated at the same time: the mutual induction of the convolution must therefore be taken into account. To calculate the coefficient of mutual induction would involve the calculation of the mean geo-

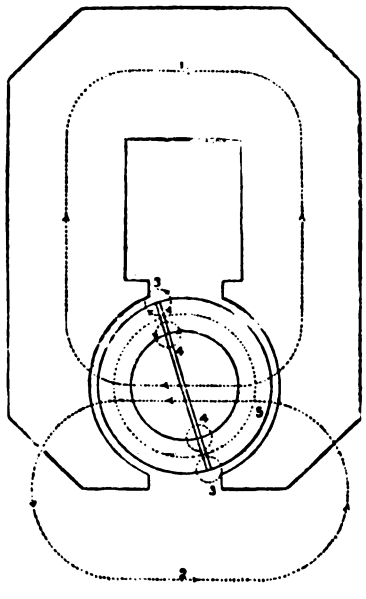

Fig. 5.

metrical distance. It will be near enough for the present purpose if the mutual induction is taken at

$$M = 38\int_{1}^{5} \frac{4\,d\,r}{r} \times 10^{-9} = 244 \times 10^{-9}.$$

The active part of the convolution may therefore be taken as having a self-induction of 594×10^{-9}. It is more difficult to get an idea of the self-induction of the end plates. The end plates are flat copper, probably 3 cm. or so wide; they are not close to the iron of the armature, but are among other plates, which lessen the effect. Probably $L_2 = 24 \times 10^{-9}$ for each end will be nearly correct. The coefficient of self-induction of a convolution is thus 1,236. The resistance of the convolution is ·000456 ohm. If the brush covers one section and a-half, the time of short-circuiting is ·001875. From these data the electromotive force necessary to bring the current to 200 amperes can be determined—

$$E = \frac{CR\epsilon^{-\frac{RT}{L}}}{1-\epsilon^{-\frac{RT}{L}}} + \frac{CR}{1-\epsilon^{-\frac{RT}{L}}} = \cdot274 \text{ volt.}$$

As the velocity of the conductor is 527 cm. per second and its active part is 76·2 cm., the field needed to reverse is $B_g = 685$.

It must be borne in mind that this calculation is at best only a rough approximation. In the first place, the field is not really uniform. In the second, the convolution has not really a constant coefficient of self-induction, as that depends on the position of the active part of the conductor in the field, and on the magnetisation of the iron in the armature in its immediate neighbourhood.

If the machine were made with two convolutions per section, and if the brushes still covered one section, it is obvious from the formula that the field necessary to reverse would be twice what it was before, if the self-induction is four times. As a matter of fact, the self-induction would not be nearly four times, for the conductors are too far apart. It would be somewhere between twice and four times.

If there were no self-induction the field necessary to reverse would be just enough to preserve a current of 200 amperes against the resistance of the convolution. If the brush surface were the same the convolution would be short-circuited for, say, 1-40th of a revolution. The loss of power would then be 28 watts. The self-induction prevents the current reversing instantaneously, and makes it change gradually. This reduces the power to about one-third, so 18 watts is about the loss of power due to the short-circuiting of the convolution. The self-induction of the section is thus instrumental in preventing waste of power.

The field necessary for the reversal of the current in a section being known, the position of the brushes can be determined.

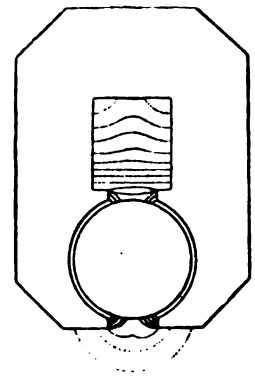

Fig. 6.

If the armature had no current the field would fall off very quickly round the armature after emerging from under the pole-pieces. At no load, for instance, the disposition of the lines of induction is, roughly, as shown in Fig. 6. In this case the lines that enter the armature are all cramped together at the pole corners. The lines leaving the shanks of the magnets pass right across and do not enter the armature at all.

If the cross current-turns are alone considered, a disposition, roughly, as shown in Fig. 7 is obtained. There are no lines across, so the lines are cramped together where they leave the armature only. If Figs. 6 and 7 were superposed, the opposite inductions

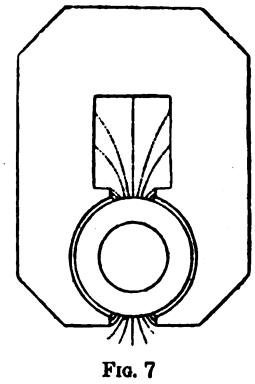

Fig. 7

would be equal quite close to the leading pole corners. The exact position would be difficult to determine, but by such a rough method as that just described the position can be found so as to make no sensible error in the calculations. Fig. 8 shows the disposition of the induction due to the back current turns. Those going right round the field are left out, for their disposition is almost exactly the same as that of the field lines, and they are cancelled by some of the series winding. If Fig. 8 is superposed on Fig. 6 or 7, the induction is increased on one side and decreased on the other. On each side of the centre line the addition or subtraction is uniform. It is clear, then, that except in the case of very small machines, or machines with very light loads, the position of non sparking of the brushes is close under the leading pole corners. In practice, this is easily verified by taking two pilot brushes and a detector, and finding the position of no deflection when one is slightly in advance of the other.

Digitized by Google

A glance at actual machines shows that the conclusion here arrived at theoretically—that the brushes are almost under the leading pole corners—is correct. The angle of lead of brushes at full load thus depends on the pole angle, and the back potential, Ω_b, can now be given in the form $(\pi - \theta)\, n\, C/10$.

Equation (5), for the full load excitation, can therefore be written,

$$\Omega_{a-m} = l_a B_a/\mu_a + (\pi - \theta)\, n\, C/10 + g\, B_g + l_m B_m/\mu_m \quad . \quad (8)$$

Equation (2), for the cross-sectional area of the field magnets, also becomes, in full,

$$A_m = 2\, a\, b\, \frac{B_a}{B_m} + r\, \frac{l\, B_a/\mu_a + g\, B_g + (\pi - \theta)\, n\, C/10}{M\, B_m} \quad . \quad (9)$$

Probably the greatest problem that still remains to dynamo makers to grapple with is that of lessening or avoiding sparking at the brushes. At present it is necessary to move them whenever the

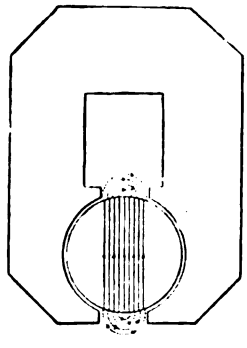

Fig. 8.

load of the machine is altered. Several methods of moving the brushes automatically have been proposed, and perhaps used, in the United States, but they have not come into common use in this country. An attendant is therefore necessary if the brushes are to be kept in good order. Fig. 9 shows a few turns of a winding specially designed to need very little moving of the brushes. A convolution, instead of being wound over the armature diametrically as usual, is wound over the core so that one side of it gets into the field just as the other side is coming out. At no load the convolution is commutated when the sides are at equal distances

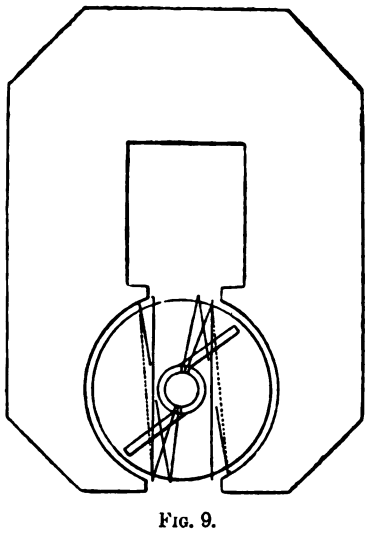

Fig. 9.

from the pole-pieces. At full load a very small movement of the brushes is enough to bring one side out of the field and put the other side in far enough to reverse the current. If the brushes are not shifted, the conductors in the belt between the pole-pieces have current in alternate directions, so that they do not act as the coils of an electro-magnet; the cross induction just under the pole corners is, however, the same. As the lead of the brushes is very small, the back current-turns are small also. As the change of field is rapid, it is necessary to use very narrow brushes at light loads, while there is sparking if there is the least inaccuracy. This winding is not perfectly suitable for very large machines with single magnets, for one conductor has its current reversed by the top leading pole corner, and the other by the lower one, and, as already explained, the top is generally stronger, so that more lead is needed on the bottom brush, and this is troublesome. In small machines this does not take place to the same extent.

In some types of machines made in the United States a series coil is wound round the armature instead of on the field magnets. It is then sometimes wound obliquely, so that it lies against the two trailing pole corners. The idea in arranging it obliquely is, no doubt, to counterbalance the obliquity due to the armature current in some way. If the series coil is wound on the armature, it must have enough ampere-turns to counterbalance the back current-turns on the armature, and, in addition to this, enough to increase the armature induction enough to allow for the armature resistance at full load. In a large machine, therefore, it is equal to but little more than the back current-turns. As it is arranged obliquely, it also counteracts part of the cross current-turns; but as the cross current-turns are always much more numerous than the back current-turns, the series coil in this position lessens the cross induction to a very small extent. This arrangement has therefore little advantage.

As a very weak field is enough to reverse the current in a section, a small pole-piece might be so applied to the armature as to reverse the sections at any convenient place. If the reversal could take place in such a position that the brushes would have a negative lead, the back current-turns would be converted into forward current turns, and a machine could be designed to give constant electromotive force, or even a higher electromotive force at full load, without any series winding on the magnets at all. Reversing pole-pieces, as they are called, were brought out some two years ago. Fig. 10 shows a simple case. Two reversing pole-pieces are shown. In order that there may be some induction in the same direction as that in the left limb of the magnet, it is clear that the line integral of the magnetic force from A to B must be positive. If the brushes are under these reversing pole-pieces the line A B passes through the neutral points, and the cross potential is $\pi\, n\, C/10$. Each reversing magnet must therefore have $\frac{1}{8}\, n\, C$ ampere-turns on it to counteract the cross current-turns, and a few more to cause the reversal. In large machines these pole-pieces are thus difficult to work in.

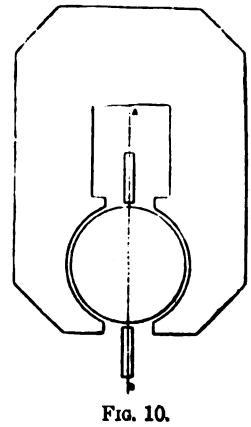

Fig. 10.

In a drum armature it would not be necessary to have two reversing poles; one wound with a little more than $\frac{1}{8}\, n\, C$ ampere-turns would be enough. Of course these poles should have their coils in series with the armature, so that their excitation varies with the cross-current turns.

If the reversing pole-piece A is made larger, and attached to the yoke, the same number of current-turns is necessary, as the yoke is at the same magnetic potential as the centre of the armature, if the magnet limbs have equal coils, and the left pole-piece is not highly magnetised. As the reversing pole needs no excitation at no load, the shunt must be wound on both limbs equally. But the series coils may all be wound on one limb so that the yoke is not at the same potential as the centre of the armature at full load. Suppose the series coil has $n\, C/16$ ampere-turns on each former, with no reversing pole-pieces, the whole may be put on one former, and the reversing pole-piece then requires but little wire on it. But the reversing pole-piece does away with the need of much series winding on the fields, so there would not be anything like these series current-turns to be arranged at pleasure; in fact, if the reversing pole-piece were put on one side, so as to give negative lead to the brushes, there would be no need of any; and for this reason the reversing pole-piece is, in large machines at least, somewhat impracticable.

Fig. 11 shows an arrangement in which a small horse-shoe electro-magnet is arranged against the uncovered part of an armature. The horse-shoe, as a whole, provides a convenient path for the line of induction due to the cross ampere-turns. If the electro-magnet has more ampere turns on it than there are on the part of the armature covered by it, one pole of it will act as a reversing pole-piece. This electro-magnet is a little difficult to attach to the dynamo so as not to cause excessive magnetic leakage, as the sides of it come near the main poles of the dynamo.

Digitized by Google

Fig. 12 is a diagram of another method. The armature proper is made as usual, but the connections to the commutator pass over the outside of a sort of subsidiary armature core. The electromotive force needed for reversing a section is induced in the connection by a subsidiary field-magnet with narrow pole-pieces, as shown. The little field-magnets are wound in series with the main circuit. The connections are shown embedded in the core as in the notches of a Pacinotti armature. A small yoke is shown in Fig. 12; in practice the subsidiary magnets would be mounted on the bedplate.

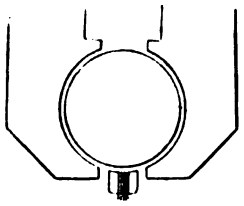

Fig. 11.

Fig. 13 shows an arrangement in which the subsidiary magnets are mounted on the rocker that holds the brushes, so that the machine can be regulated by moving the brushes backwards or forwards without producing sparking.

It is probable that some form of reversing pole-piece will come into general use, so these forms are described at length.

The advantages to be gained by such an arrangement are very great. The brushes do not need to be shifted as the load varies, which saves attendance and wear. Back current-turns are avoided, and this reduces the expense in the series field windings, and saves

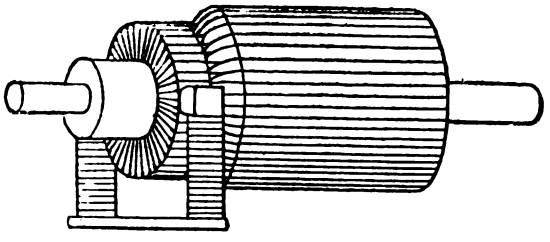

Fig. 12.

power now wasted in them. The field magnets can be made smaller, and the induction in them will be the same at full load as at no load, so that the electromotive force will not be unstable at light loads—a state of things which is not always avoidable at present.

A smooth-surface commutator, such as is generally used in low-tension dynamos, is seldom used on machines for arc lighting. No doubt the reason is this: An arc light machine must be series-wound, because it would be too expensive to wind the field magnets with small enough wire to act as a shunt. Though series-wound, it

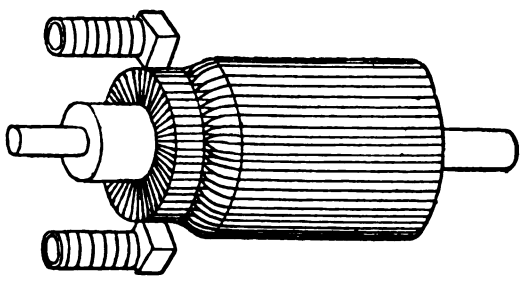

Fig. 13.

must be arranged so that any increase of current is accompanied by a decrease in the electromotive force, or the lamps would flicker. The point of no sparking, therefore, shifts forward when the current increases, and backwards if the current decreases. There must be a large number of turns per section, so that the least movement of the non-sparking point causes sparking at the brushes. If the current of the machine increases above the normal, so that the brushes are no longer far enough forward to avoid sparking, the spark caused remains as a small arc till the current in the conductors of the section comes to the normal, and then disappears. If the machine current falls below the normal, the current in the section will have increased beyond the armature current, and the arc so formed may continue long enough to burn the commutator sections, or even to flash round. In machines with very few commutator sections the brushes are always given too little lead, otherwise there would be a flash round every time the current fell below the normal. No doubt this is why the practice in arc light machines is to use few commutator sections, to leave a small air space between them, and to give the brushes less than sparkless lead, so that the sparks then form between the end of the brush and the edge of the section, and do not destroy the surface of the commutator, and do not flash round. In spite of this, however, arc light machines have been made for some time with continuous-surface commutators.

Gramme and Drum Armatures.

The drum armature was invented by Worms de Romilly, and in 1872 an account was published in *Les Mondes*.

First, as to winding. If a given armature is wound Gramme or drum, with a given number of external turns, there is less resistance in the drum, unless the armature is of very large diameter in proportion to its length. If the discs are made specially for a drum armature, a greater radial depth can be allowed, as the space used for inside turns in the Gramme can be utilised for iron.

If the radial depth of the disc is greater, and the induction in the iron of the armature is the same, the induction in the air-gap is greater. This takes heavier field-magnets and more excitation, but increases the output of the armature. In addition to this it admits of more armature current-turns, as the cross induction can be increased also without reversing the induction under the leading pole corners. With a drum armature a very much larger single-magnet machine can therefore be built than with a Gramme.

Each section of the Gramme machine has a higher resistance than that of a drum with the same number of commutator sections. If a given armature is wound Gramme instead of drum, the self-induction is about double for each external turn, because the conductor also makes a little field of its own inside the armature, as in Fig. 3, being close to the iron, and the self-induction due to that would be about equal to that of the active part of the conductor. Two turns per section make the self-induction from three to four times as great as it would be with one turn. There is no mutual induction between the conductors in connection with the opposite brushes, as in a drum machine, so the self-induction in the Gramme may be taken as twice that of the drum. The Gramme may, however, be made with twice as many commutator sections, giving one turn per section. The self-induction of a section is thus greater than the self and mutual induction of half a convolution in the drum, and the resistance is also greater. The Gramme therefore, still requires a stronger reversing field. The effect of this is that a small displacement of the brushes—or, what is the same thing, a small variation of the load—causes a greater spark at the tip of the brush. If the armature is perfectly symmetrically made a position of no sparking can be found for any given load with a large number of turns per section, but the least variation of load or movement of the brushes will then give rise to sparking.

The Gramme has still another great disadvantage when used in large machines. The current-turns on the armature bring the sides of the internal hole to a considerable difference of magnetic potential, and this causes induction in the spindle, and heats it. This not only causes waste of power, but frequently the heat is conducted to the bearings and initiates hot bearings in addition. In a drum armature the sides of the inside hole have only a difference of potential of $l_a\ B/\mu_{a'}$, as the armature current-turns do not affect the spindle. The armature can generally be made of such radial depth that it is slightly magnetised, while a Gramme armature is generally taken up as high as consistent with keeping cool and economy of field-wire. The induction due to the back turns in the central hole in a Gramme machine introduces a correction in the size of magnet iron, as it acts as waste field. The induction in the hole is really oblique, and is due to the whole of the armature current-turns, so that the leakage is often very serious.

The drawbacks to the drum armature are all mechanical. In small drums the difficulty of winding, the want of ventilation at the ends, and the difficulty and expense of repair, more than balance the advantages of small resistance and little wire, or large output.

In large machines the same drawbacks appear, but they are of less relative importance. Without doubt the large dynamo of the future will be a four-pole or six-pole drum. By using four poles a much larger machine can be made without trouble from cross-induction. The end connections, which are the greatest difficulty, then become much simpler, and any part of any convolution can be taken out for repair without disturbing the rest of the conductors. The central ventilation hole is much larger, as the radial depth need only be half what it is in a twofold machine.

Relation of Motors to Dynamos.

Having discussed the full theory of dynamos, its application to motors is, of course, exceedingly simple. A motor is nothing but a

Digitized by Google

dynamo running the other way, as a dynamo is a practically reversible machine.

Fig. 14 shows a dynamo armature with the position of the brushes and the back and cross armature windings. For simplicity the brushes are shown as touching the outside of the armature instead of the commutator.

Suppose the direction of the currents in the field and armature to remain the same, but the direction of rotation of the armature to reverse, the dynamo then becomes a motor. The brushes must be inclined the other way, as shown dotted, otherwise the ends would catch in the commutator. The cross and back turns remain as before, so that the armature current opposes the field excitation. The brushes would be in exactly the same place in the motor as in the dynamo if the field where the commutation takes place were uniform. As a matter of fact, it is stronger near the pole corner, so a motor has a very little less lead. It has sometimes been said that the armature current assists the field in a motor, but this can only take place if the brushes are given a negative lead. The same result is obtained in a dynamo by putting the brushes back; but in both cases, of course, this leads to excessive sparking. It is sometimes imagined that some effect of the convolutions being commutated acts differently in a motor, but a glance at the diagram shows that the action is completely reversed. The section being commutated in a dynamo, opposes the movement of the armature; in a motor it assists the armature. No appreciable Foucault currents can be caused by the reversal of the section. If any were, they would assist the dynamo and oppose the motor, so that they would also be reversible.

Most writers on dynamos speak of loss of electromotive force and loss of power by "self-induction of the armature." This is often supposed to amount to about 5 or 10 per cent. There must

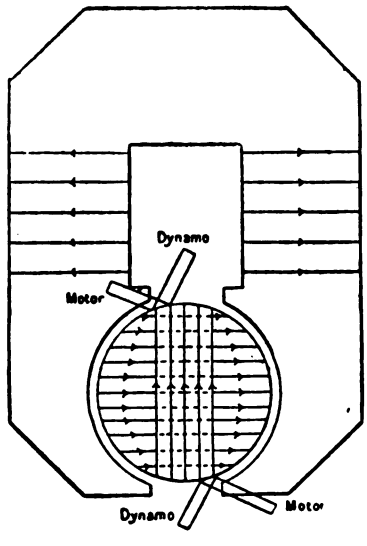

FIG. 14.

be some misunderstanding about this, as there is no way in which such a loss could take place. The current in the armature is sensibly constant except in the section being commutated. In any case power cannot be lost by self-induction.

There is, then, no point in which the dynamo is not perfectly reversible, except a merely theoretical difference in the position of the brushes, and there is no foundation for the idea that a motor should have a large armature and a weak field. In so far as any motor departs from the design of a good dynamo, it is bad.

Of course the winding of the field-magnets in a motor is different.

The winding and design of magnets of motors have received but little attention. Suppose a motor is to run at constant speed on a constant-potential circuit. The shunt excitation is

$$\Omega_s = l_a B_{ao}/\mu_o + g B_{go} + l_m B_{mo}/\mu,$$

the suffixes o and f showing reference to full or no load.

At full load the armature induction must be reduced so that the full-load current passes. If E is the terminal electromotive force, and R the armature resistance, the armature induction at full load $B_{af} = B_{ao} \frac{E - CR}{E}$, and the gap induction is also reduced in the same proportion. The full-load magnetic potential of the field coil is

$$\Omega_{s+m} = l_a B_{af}/\mu_a + (\pi - \theta)(n C/10 + g B_{gf} + l_m) B_m/\mu_m \quad . \quad (8)$$

The alteration of the first and last terms makes so little difference to the value of Ω_{m+s} or Ω_s that it may be disregarded. The full-load excitation is thus increased by $(\mu - \theta) n C/10$, and decreased by the difference between $2 g B_{go}$ and $2 g B_{gf}$. That is to say, extra field excitation is needed to counteract the back current-turns on the armature, and less excitation is needed to produce the reduced air-gap induction. If these are equal, the machine will keep constant speed when shunt-wound. In a small or slow machine the armature loss is large; in a large one the back induction is great. A small machine, therefore, needs backward-wound series coils, and a large one forward-wound. If $(\pi - \theta) n C/10 = g B_{go} - g B_{gf}$, the shunt ampere-turns needed at no load and full load differ only by the difference of excitation needed to magnetise the iron of the field-magnets and armature. Unless the machine is very small, the difference in the armature and field induction is not important. It tends to make the motor run slower at full load, and this may be taken into account where very exact work is needed.

As the field induction in a motor is highest at no load, the area of cross-section is

$$A = 2 a b \frac{B_a}{B_m} + \frac{r \Omega_p}{M B_m} \quad . \quad . \quad . \quad . \quad . \quad (2)$$

it is thus somewhat smaller than in the case of the corresponding compound-wound dynamo.

As a shunt machine is simpler to make than a compound, and as a differentially wound motor may start backwards, shunt-winding is preferable. Within wide limits of size constant-speed motors can be designed with simple shunt-winding. All that is needed is to make Ω_b equal to $g B_{go} - g B_{gf}$. $\Omega_b = (\pi - \theta) n C/10$, and $B_b = \frac{2 a b B_a \pi}{(a+d)(r+\frac{1}{2}g)\theta}$, where d is an allowance for fringe, and θ is also made a little large to allow for fringe. This gives

$$\pi\theta - \theta^2 = \frac{20 a b B_a \pi}{(a+d)(r+\frac{1}{4}g) n C} \quad . \quad . \quad . \quad . \quad (10)$$

This appears complicated, but when the symbols are replaced by numbers for an actual machine, of course it is quite simple. It will be found that in very small motors this makes the pole angle too small, while in large machines the pole-pieces would embrace the armature so much as to cause excessive magnetic leakage and reversed induction under the trailing corner, unless the pole-pieces are designed to obviate this.

A properly designed direct-current motor has also the very convenient property of running at approximately constant speed, even if the electromotive force on it varies. If the field and armature are not highly magnetised the armature induction varies approximately as the electromotive force on the shunt. The armature induction, and, consequently, back electromotive force, of the machine thus varies as the electromotive force on the mains, which is just the condition wanted for constant speed. A direct-current motor will therefore preserve approximately constant speed, not only with varying load, but also with varying electromotive force.

SMALL AIR SPACE DYNAMOS.

There is a type of machine that has not yet been much studied; that is the dynamo or motor in which the gap is kept small, being merely a mechanical clearance to allow the armature to rotate.

Obviously, as the air space is small, the magnets will need very little excitation, and there will be no waste field to speak of; so the magnets may be made exceedingly small and light, though that does not appear to have been generally realised. The Pacinotti is the best known form of this machine, the Brush being a good example. The drawback to the Pacinotti armature is that it gives rise to Foucault currents in the field-magnets, and for that reason it is not generally used now, though the difficulty is sometimes overcome by making the teeth small and numerous.

Machines with the armature wires wound through holes near the periphery have been made on the Continent, but apparently with the view of increasing the armature induction by reducing the air space. This form, however, admits of very small field magnets with very little excitation, so that it is specially adapted for machines where extreme lightness is needed.

At full load, however, a trouble arises in small-gap machines. As the air space is very small, the cross induction is very great, and so the induction under the leading pole corner is reversed. Of course there is a position of the brushes with no sparking, but it is very far forward, more especially if the speed is very slow, as the self-induction of each armature section is then considerable. The result is that the back current-turns are very great, and so the field magnets necessary for full load are not so very small after all. If the dynamo is running at a very slow speed—such, for instance, as a motor on a tram-car at 200 or 300 revolutions—the brushes may be allowed to spark, as the sparking will be small, and given no lead, or just enough to preserve constant speed. This form of machine is suitable for the application of reversing pole-pieces. It was shown that in any ordinary machine the difficulty of designing reversing pole-pieces arises from the difference of magnetic potential between the pole-pieces and the armature. In this machine the

Digitized by Google

difference is very small, so reversing pole-pieces can easily be applied.

In the case of the Brush machine the cross induction is enormous, and the back current-turns are therefore enormous too. The result of this is that the lead of the brushes is very great. Such a machine may be short-circuited without any dangerous increase of current. In fact, it has been used for charging batteries for train lighting at varying speeds. As the speed increases the current tends to increase, and reduces the armature induction enough to keep the current within safe limits, even if the speed is increased several fold.

The excessive heating of the trailing pole corner in the Brush machine has given rise to many speculations. It has generally been assumed that the heat generated there is no greater than at the leading pole corner, but that it is additionally heated by the hot air from the armature. It is more probable that the excessive heating is due chiefly to increased Foucault currents. As the brushes have considerable lead, the coil leaving the trailing corner is not in parallel with the other, so that the heating by Foucault currents in the trailing corner would be nearly four times as great as under the leading corner where two coils are in parallel. The iron is probably too highly magnetised to allow the induction to vary quite so much as this, and as it is cast iron the resistance prevents the heating being still greater. The trailing corner is also very highly magnetised, while the leading probably has its magnetism slightly reversed. The heating from variation of magnetisation at the trailing pole corner is thus much greater, especially when the enormous magnetic force is considered, and the frequent passage of the armature notches. A 40-lighter has something like 120 per second.

As a Brush machine has very little air space, the shunt is very small, so that the compound machine is chiefly wound with series wire.

Correction in Testing Gramme Machines.

In the method of testing machines by running them as motors at no load, the machine is run as a motor with the armature induction the same as at full load. The power taken to drive it gives the stray power, *i.e.*, the loss of conversion. To this is added the loss by resistance in the armature and fields, and the efficiency of the dynamo or motor is thus calculated. The stray power consists of loss by mechanical friction, the loss by reversal of magnetisation, and loss by Foucault currents, and it has been assumed that these remain constant if the armature induction is constant. The theory of armature reaction, however, points to a few corrections. The loss by Foucault currents in the armature conductors is greater at full load than no load, by at most 33 per cent. The loss by reversal of magnetisation may also be slightly greater, as the induction in some parts of the armature may be greater. The loss by Foucault currents in the discs is slightly greater, but as this loss is exceedingly small, that does not matter. These increased losses are of little more than theoretical importance, but it is as well to point them out. If the machine is a large Gramme, the heating in the centre is largely increased at full load, so this method of testing does not give perfectly reliable results in the case of such large machines. For small machines and large drum machines it is very convenient.

This Paper has been devoted to direct-current dynamos, as the corresponding treatment of alternating-current machines is, perhaps, hardly ripe for discussion yet, though it is of enormous importance, as the whole theory of running machines in parallel, and of alternating motors, depends upon it.

After the reading of Mr. Swinburne's Paper, it was announced that at the next meeting (Thursday, February 20th), Mr. W. B. Esson would read his communication on "Some Points in Dynamo and Motor Design," and that the two Papers would then be jointly discussed.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

New York, *February* 8, 1890.

The Gas and Electric Light Statistics of Massachusetts.—Some interesting statistics on the subject of gas and electric lighting have just been published in the fifth annual report of the Board of Gas and Electric Light Commissioners of Massachusetts. It is generally known that the electric light is a favoured illuminant in the New England States, but it will occasion general surprise, I believe, to state that there are more electric light and power companies in Massachusetts now than there are gas companies. Probably this can be said of no other part of the world, although such a state of affairs may be closely approached in some other of our progressive commonwealths, such as New York, Pennsylvania, Illinois, and Nebraska. It appears that in Massachusetts there are 100 electric light companies and 75 gas companies; while of these 75 no fewer than 26 have obtained the power to supply electricity as well as gas, so that they should really rank as electric light companies. It appears, moreover, from these figures that in the department of public lighting, electric lights are steadily displacing the gas lamps, and the coal gas companies are shown to have lost just upon one thousand lights from this cause during the year. Summing up the figures roughly, they show that there are about 83,000 incandescent lamps in operation in the State, and about 11,500 arc lights. These figures are more significant when it is remembered that the Commissioners are a body vested with quite considerable powers in the way of checking irresponsible competition; in other words, when they are satisfied that a community is supplied with adequate agencies for producing light and which are furnishing light at a reasonable rate, they can prevent the starting up of new competition, which would lead at once possibly to a reduction of rates, but which very probably would ultimately result in a combination, when the community would have to pay higher rates permanently on the consolidated capital. Hence the electric light statistics are those of a solid, stable industry.

New Applications of the Electric Motor.—There is considerable activity in the electric motor field, not only in the direction of new motors, but in the applications to a number of industries. An event which has attracted no little attention in Chicago recently, and is being commented upon by the mechanical journals of the country, shows what the gain in convenience sometimes may be where resort is had to the motor. A large printing establishment in that city was suddenly deprived of its power by the complete wreck of its engine and boiler from a boiler explosion. Had it been necessary to wait until new boilers could be set up and the engine repaired, the company could not have resumed operations for several weeks, and the delay would have been attended with serious loss not only to the company but to their customers and *employés*. As soon as the situation was fairly grasped, however, it was decided to put in a 40 horse-power Thomson-Houston motor and to connect it to the main shafting. This was done: the circuit was run to the motor, and the whole printing establishment was started again in a day. It is such an exemplification as this of the handiness of electric power that recommends it so generally for all manner of industrial uses. Among the new motors which have just been put upon the market may be mentioned the small Crocker-Wheeler for incandescent circuits. Hitherto, in small motors of this kind, the practice has been in varying the speed to throw in a resistance in the main circuit, consisting usually of a lamp mounted on the top of the motor. By means of a new winding and switches to correspond, this necessity is avoided, and the speed can be varied between 1,900 revolutions full speed, and 950 half speed, without any loss in efficiency. It is interesting to mention that owing to the care with which this motor has been worked out and built, the speed can be employed as an indicator of the pressure on the circuit. Thus, if the speed of the motor is much greater or much less than is marked on the name-plate, that fact shows the circuit to be unsuited for it. This may then be determined quite accurately by counting the speed of the motor when oiled and run with the belt or load thrown off. It then runs 200 revolutions faster than the speed given off on the name-plate, and any difference from that speed shows that the circuit is of correspondingly higher or lower E.M.F. Thus a motor marked 110 volts, 1,900 revolutions, should run free at 2,100 revolutions. If it run free at 2,000 it shows that the circuit is only about 105 volts, and should be altered accordingly. Another interesting little feature is the simplicity of change of direction of rotation. All that is required is merely a change of the position of the brush-holders, putting the upper one below.

Among the newer applications that have recently been brought out is the Kinsman ice-cutting machine. As you are probably aware, ice-cutting is quite an industry in this country when there is any ice to cut, and, in point of fact, there are several sections of the far North which depend on the ice crop just as much as do our Western prairies on their wheat crops. So far, the horse has been the general source of power for running the ice-cutting machine, but it seems as though electri

Digitized by Google

city is likely to enjoy some popularity in this field, especially as very large numbers of the ice companies operate electric light plants, so that, when ice-cutting is actually going on, all the ice may be gathered in, day and night, before the thaw comes and the ice gets too thin to be of much use. It is evidently very easy to take the same generating plant and to run it for motive-power purposes during the day. The apparatus rigged up by Mr. F. E. Kinsman, of this city, consists of an electric motor, suitably mounted upon a pair of spurred wheels, upon the inside of which is placed a ring gear. The shaft of the motor armature is of sufficient length to allow the small pinions on its ends to engage the ring gear for the purpose of propelling the carriage or carrier. Upon this armature shaft are placed the cutters or saws in gangs as required. There is thus a fixed relation between the progress of the carriage and the speed of the knives or groovers, the same being true of the cable drums, whose shafts for obvious reasons carry a much larger pinion than the armature shaft. These drums pay out a specially constructed cable or conductor, so as to follow the motions of the machine, back and forward. This machine, all told, weighs less than a good-sized horse, and at the same time has the advantage of having its weight better distributed, proceeding also without shock or pounding. It requires but one operator, and is easily moved about from pond to pond. It is claimed that a 2-knife cutter can do the work of 25 horses, each requiring a leader and a ploughman. Thus you will see that in the near future the average American citizen will not only be fanned electrically in the heat of the summer days, but sip cool drinks for the ice of which he is also indebted to electric power.

Electric Railroad Development.—The continued extraordinary mildness of the winter has had a most stimulating effect on the electric railroad industry, and from every quarter one hears of great progress in this direction. I made reference recently to the action of the Minneapolis Street Railway Company in throwing aside a cable plant worth $400,000, quite new, and substituting electricity. The company has now ordered a large number of cars from the Thomson-Houston Company, and the work will be proceeded with without delay. It is stated that the order from St. Paul and Minneapolis for electric railway work given to the Thomson-Houston Company aggregates two million dollars. This, however, is only the initial equipment, so you will see that in this country the business is already going into large figures, such as may fairly be compared with those of the long steam roads. Speaking of steam railways reminds me that in Cincinnati, where the electric railroads have been working very successfully, a proposition has been seriously discussed by the local papers to run the suburban trains into the city by means of electric power, thus doing away with the various objections that prevail against the use of steam within the city limits. I should not be surprised to see some such change made in Cincinnati at an early date. When people once begin to discuss such matters in this country, they are not satisfied, as a general thing, until the change is made.

The Production of White Lead by Electrolysis.—An interesting process has recently been made public by Mr. T. D. Bottome, for the production of white lead by electrolysis. His process consists in electrolytically dissolving a lead electrode in an electrolyte containing nascent or free carbon dioxide, whereby the lead compound formed by electrolytic action is precipitated to form hydrated carbonate of lead, or pure white lead. It is, of course, necessary to have the bath replenished with additional carbon dioxide as the process continues. This can be done in several ways, a convenient one consisting in burning limestone, washing the gas produced by the dissociation of the constituents of the limestone, and supplying the gas directly to the bath. The white lead is from time to time removed from the tank, washed, and dried; and upon mixing with a suitable vehicle into a paint, it is found to have much greater covering properties than ordinary commercial white lead formed by dissolving lead in acetic acid in the presence of carbonic acid, since the latter is slightly crystalline and less opaque than the hydrated carbonate produced by the action of carbonic acid on plumbic acid. The samples of this white lead are remarkably good, being an extremely fine powder, the result of a simple drying by spontaneous evaporation, in marked contrast to the white lead obtained by the old acetic acid process, which has to be ground up mechanically before it can be used. Mr. Bottome figures that, with power at $55 per horse-power a year, 50 cents a ton for the electric current would cover that item in the making of white lead. Upon this and various other data—which, however, include the somewhat specious element of "valuable by-products"—he claims that it is cheaper to produce the white lead this way than by time-honoured methods. It is to be hoped that this may prove so, for the resultant material is undoubtedly far above the average.

The Convention of the National Electric Light Association at Kansas City.—A good deal of interest is taken in the Convention of the National Electric Light Association which takes place at Kansas City next week. Although it is mid-winter, there is no question as to the large attendance at the Convention, as Kansas City is the centre of a remarkably wealthy and progressive district, and touches a large territory which is still practically unoccupied in an electrical sense. It is worthy of note that the headquarters of the Convention will be established at the Coates House, built by one of the pioneers of the city, Colonel Coates, who was largely interested in the introduction of the Edison electric light in Kansas City. It deserves mention, as evidence of the perfect faith of this man in the future of electricity, that when he built his fine hotel in 1886 he had it wired throughout for incandescent lights, and refused to have a gas-pipe placed within the building. At the present time Kansas City has half-a-dozen good electric light plants, including a large Thomson-Houston station and a large Edison station. It is also becoming an excellent centre for the distribution of general electrical goods, so that one or two supply houses have already been started there.

A Demand for Electric Traction Data.—The Western Electric Railway Association held their meeting in Chicago last week, and at that time appointed a Committee to compile such statistics as could be obtained covering the operation of electric railways in this country. The first thing that they wished to ascertain, on the testimony of representative superintendents of railway lines, was the comparative cost of operating by horses and by electric power. Another point was as to the mechanical repairs required on motor cars, with special reference to types of gearing and their relative efficiency, noiselessness, &c. The third point was as to repairs required in the electrical apparatus and the overhead circuits. Another matter they wished to determine more clearly was the comparative depreciation in value between lines operating electrically and by animal power. Yet another point of no small importance was one with regard to the prevailing value of safety breaks and the results obtained with them, as well as the cost and the nature of their material and construction.

CORRESPONDENCE.

THE ECONOMIC RATIO OF A TRACTION SYSTEM.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I notice in your issue of January 17th a correspondent raises some questions concerning the economic ratio of a traction system mentioned in some recent Papers of mine. If by the economic ratio I had meant to designate the dividend earning capacities of various motor systems, I should have been obliged to include a large number of variable factors quite outside of the question under discussion. Your correspondent points out that his own suggestion for the economic ratio is open to the same objection. I therefore confine myself to the ratio between total weight and useful load, taking into account the commercial efficiency of the motor system used. I included the weight of car in the useful load for the obvious reason that the car is necessary for the transport of passengers, and carring the car over the line is as necessary to earning dividends as carrying the passengers. If your correspondent will kindly suggest a method of seating passengers on material

Digitized by Google

particles, or "the meaning of words," I shall make no further reply to his criticism.

The form of economic ratio which I used was intended to mark the difference in the power supplied to a car by various motor systems, and for no other purpose. In certain cases it might be desirable to employ a ratio containing one or many other factors, and if the nature of the discussion required, I should not hesitate to do so.

As carrying on a discussion at a distance of 4,000 miles is not altogether convenient, I trust that this explanation will prove sufficient.—Yours, &c., LOUIS BELL.

Chicago, February 6th, 1890.

PROF. AYRTON'S PAPER "ON GALVANOMETERS."

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your last issue, in giving an account of the discussion on the Paper on "Galvanometers" at the Physical Society on 7th inst., Prof. Ayrton is reported to have said:—

"The values in the case of No. 3 were deduced from Elliott's data obtained by testing with a Standard Cell which they believed to be a Daniell, but that it was quite possible a Grove cell might have been employed, as he believed this was Messrs. Elliott's usual practice."

On reading this, we wrote to Prof. Ayrton on 15th inst., asking him whether he had been mis-reported, but not having received any reply up to the present time we feel justified in assuming your report to be correct.

It is amusing to find that the learned Professor does not give us credit for knowing the difference between a Grove's and a Daniell's cell; but we may be allowed to express our surprise at the belief expressed by Prof. Ayrton, after a correspondence which took place between Mr. Mather (one of the authors of the Paper) and ourselves. On January 31st Mr. Mather wrote to ask if, in the values we had given, a Daniell's or a Grove's cell had been used, to which we replied that "For the last 25 years at least it has not been customary to use any other cell than the Daniell's in testing for the figure of merit;" and yet, in spite of this assurance, Prof. Ayrton maintains, and expresses his belief, that it is our usual practice.

The galvanometers whose values were tabulated were all given from tests made with a Daniell cell. We shall therefore feel obliged if you will kindly insert this letter in your next issue, in order that your readers, who, no doubt, to a large extent are also users of our galvanometers, may be made acquainted with the facts. We have little doubt that they will be more ready to accept our assurances than Prof. Ayrton seems inclined to be.—Yours, &c., ELLIOTT BROS.

101 and 102, St. Martin's-lane, London, W.C.,
February 20, 1890.

[We would refer our correspondent to a correction of our Physical Society report, which will be found in our Notes column.—ED. *E.*]

TELEPHONES FOR DOMESTIC USE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: With reference to your concluding remarks to the article on the above subject in your issue for February 14th, perhaps you will kindly allow me to point out that as you will observe from the enclosed copy of my patent specification No. 12,823, 1887, and Figs. 11 and 12 of the drawings thereto appended, there is no novelty in the automatic switch arrangement employed by the Telephone Construction and Maintenance Company in their inter-communication switch-boards, a precisely similar device being described in my specification.—Yours, &c., A. A. CAMPBELL SWINTON.

66, Victoria-street, S.W., February 14, 1890.

[*Extract from Patent Specification.*]

In order to make these switches automatically return to the normal position, viz., the position in which they should remain when not in use, the said switches may be provided with a spring or weight, tending always to make them return to this position, and a catch arrangement may be fitted to retain the switch in any other desired position, the said catch being so connected to a hook on which the telephone is hung, that the weight of the latter when hung up will withdraw the catch and allow the switch to return to its normal position under the action of its spring or weight.

Fig. 11 shows how this may be carried out, w being the telephone hook drawn up by the spring w^2, and resting when the telephone is on the hook upon a stop w^1. The lever of the hook w has a tooth w^4, engaging with

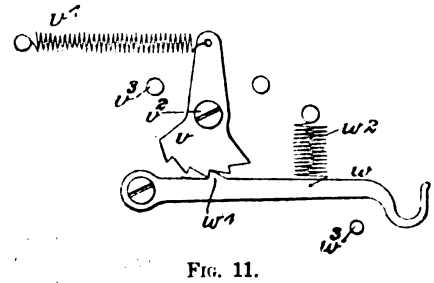

FIG. 11.

one or other of the teeth in a quadrant r, turning on a centre r^2, and provided with a spring r^4. When the telephone is off the hook the tooth w^4 engages with the tooth of the quadrant which is brought opposite it when the switch is turned. When the telephone is put on the hook the tooth w^4 releases the quadrant, and the switch is by the spring r^4 returned to its normal position. Or an arrangement similar to that shown in Fig. 12

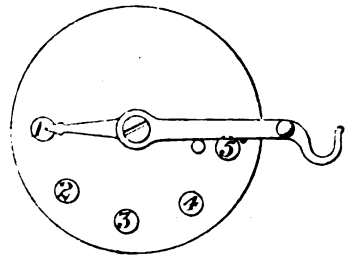

FIG. 12.

may be employed, the handle of the switch being made also the hook on which to hang the telephone receiver, and the arrangement being such that the hook is in a proper position to hang the receiver on it when it and the switch it operates are in the position that is required, as mentioned above.

[From our description (*The Electrician*, January 20, 1888) of a domestic telephone installation on Mr. Swinton's plan, it would seem, however, that no use was then made of this automatic device. "When the conversation is completed A replaces his plug in the A hole of his switch-box, so that other stations may be able to call him up if required."—ED. *E.*]

THE FULHAM VESTRY AND THE ELECTRIC LIGHT.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Yesterday's number of your valuable paper states that the Fulham Vestry have lodged objections to the two companies applying for Provisional Orders within their jurisdiction, because they do not consider the district at present ripe for electric lighting. Now, although this was mentioned incidentally as a reason, the actual determination of the Lighting Committee was to oppose any company obtaining either Licences or Orders, so that the Vestry may apply for powers and undertake the work itself. The Lighting Committee consists of 15 members, and meets weekly for the purpose of considering all questions of electric lighting in the parish. Reports as to the Vestry's powers, the requirements of the parish, and the eligibility of sites, have been received from the Solicitor, the Clerk, and the Surveyor. Each member has been supplied with the two Acts of Parliament, the Board of Trade rules, &c., and the Clerk has been ordered to place the current number of *The Electrician* on the table at each meeting of the Committee. We have also under consideration the lighting of our new Town Hall at Walham Green by electricity. In conclusion, I may add that the Committee have the sanction of the Vestry to obtain the assistance of an electrical engineer or expert to advise them generally on the subject, and are now seeking some one properly qualified for this purpose.—Yours, &c.,

RUSSELL SPOKES,
Member of the Lighting Committee
February 15, 1890. of the Fulham Vestry.

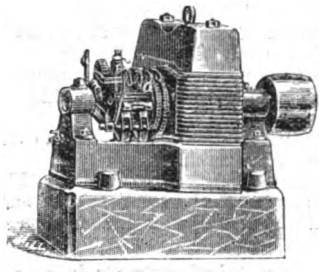
PARSONS AND CO.'S DYNAMOS AND MOTORS.

The annexed illustration shows the form of dynamo now being constructed by Messrs. C. A. Parsons and Co., of Newcastle-upon-Tyne. Great care has been taken in designing these machines to combine efficiency with strength and simplicity of construction, enabling them to stand rough usage without getting out of order.



These machines, which give good results as motors, are supplied with a simple form of brush-holder in which the springs usually employed are replaced by suitable balance weights, which have the advantage of ensuring the correct amount of pressure between the brushes and the commutator, with considerable saving in wear to both of these parts. Messrs. Parsons are also constructing machines of the inverted single horseshoe type, with similar improvements.

TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning.*]

"THE ELECTRICIAN"

ELECTRICAL TRADES' DIRECTORY & HANDBOOK for 1890

The new edition of our well-known Directory and Handbook is now ready. The book consists of 850 pages, and has entailed this year an exceptionally heavy amount of work. The HANDBOOK DIVISION contains a mass of most useful information. The DIRECTORY DIVISION consists of more than 400 pages, and contains a very carefully compiled Alphabetical and Classified List of Firms and Persons engaged in the Electrical and Allied Trades in all parts of the world. This Division has been corrected up to date, and the book is thoroughly reliable, even the very numerous changes which take place in the month of January being incorporated. The book is not a mere list of Members of Scientific Societies repeated again and again. The Colonial and Foreign Division will be found extensive and reliable. *Orders should be forwarded at once.*

MESSRS. DRAKE AND GORHAM.—This firm advise us that they are now acting on behalf of Messrs. Johnson and Phillips, of Charlton, as sole London agents for electric lighting and motive power. Their circular states that the electric light department at Charlton has recently been considerably enlarged to meet the rapidly increasing demand for dynamos and other electric light apparatus. Machines of the standard sizes will be kept in stock. The new accumulator department at Charlton is approaching completion, and Messrs. Drake and Gorham have secured the sole concession for the United Kingdom and Colonies.

DISSOLUTION.—The firm of Sydney F. Walker and Oliver, of Cardiff and Newcastle, telegraph and electrical engineers, has been dissolved.

AMERICAN CARBONS. — Messrs. Shippey Brothers (Limited) announce that they have been appointed European agents for the National Carbon Company, Cleveland, U.S.A., and that a stock of all sizes will be kept at their offices, 13 and 14, King-street, Cheapside.

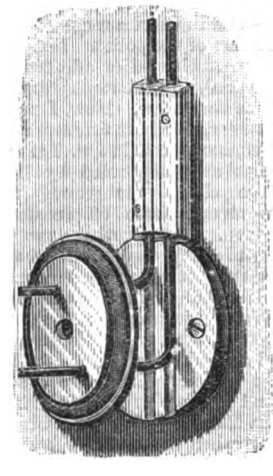
ZÜRCHER TELEPHONGESELLSCHAFT, ZÜRICH.—Dr. Albert Denzler has recently resigned the position of manager of this Company, and is succeeded by Herr Emil Bitterli, late chief engineer to the Company.

SALE BY AUCTION.—Mr. Alfred V. Robinson will offer some valuable property for sale at the Mart, Tokenhouse-yard, London, E.C., on Tuesday, March 4th, at two o'clock. The property comprises valuable leasehold electrical manufacturing premises, situated in Pownall-road, Hackney, London, together with dwelling house. Further particulars will be found on page 3 of our advertisements, and all information can be obtained on application to Messrs. Blackford, Riches, and Co., 25, Abchurch-lane, E.C.; or of the auctioneer, High-road, Tottenham, N.

AN INTERNATIONAL EXHIBITION OF MINING AND METALLURGY.—An exhibition will be held during the summer at the Crystal Palace, which has received most encouraging support. The Lord Mayor of London is patron of the Exhibition, and the Honorary President is the Duke of Fife. Among a long list of hon. vice-presidents are the names of Lord Thurlow, Sir Frederick Abel, C.B., &c., Sir Alexander Armstrong, K.C.B., &c., Sir Francis Dillon Bell, K.C.M.G., C.B., Sir James Kitson, Bart., Sir John Pender, K.C.M.G., Sir Edward J. Reed, K.C.B., M.P., Prof. W. Chandler Roberts-Austen, F.R.S., &c. Mr. W. Pritchard-Morgan, M.P., presides over the Executive Council, which consist of a number of gentlemen well known in connection with mining, metallurgical, and allied interests. The scope of the Exhibition will be wide enough to enable an interesting display to be made. Mining and scientific metallurgy, which now occupy such important positions in connection with modern industrial advancement, will have special exhibits, and one-half of the profits of the Exhibition is to be disposed of by the Council either in founding a scholarship at the Royal School of Mines, or in helping some other institution connected with mining and metallurgy, and the other half will be returned to the exhibitors. The hon. sec. is Mr. Geo. A. Ferguson, editor of the *Mining Journal*, 18, Finch-lane, London, E.C., from whom all particulars may be obtained.

IMPROVED BACK BLOCK.

Mr. Bathurst sends us an improved back block, the arrangement of which will be seen from the illustration. It consists of two pieces, the bottom one, which is grooved to correspond with the grooves in the casing, being screwed up flush underneath the end of the casing by simply sawing off a portion of the block to make it fit. This bottom block is the same thickness as the casing, and the grooves in the casing are continued in the block, so that the wires come right down into the switch, cut-out, or ceiling rose, and



are everywhere placed in wood without touching the plaster. The bottom block is covered by a polished mahogany or walnut cover, and the wires brought through as shown, and the casing cover fitted to the edge. The whole has a neat appearance, and the small extra cost of the double block is recouped by the saving of time and trouble. By using this back block in connection with Mr. Bathurst's "cross-over block" (*The Electrician*, February 22, 1889, p. 450) the wires in any installation are *everywhere* raised from contact with damp walls and plaster by the interception of dry wood.

COMPANIES' MEETINGS & REPORTS.

India Rubber, Gutta Percha, and Telegraph Works Company (Limited).

The 26th ordinary general meeting of this Company was held on the 14th inst. at the Cannon-street Hotel, under the presidency of Mr. S. W. Silver.

The SECRETARY (Mr. William J. Tyler) having read the notice convening the meeting, the report of the Directors was taken as read.

The CHAIRMAN: We have much pleasure in rendering such an account to you of the operations of the past year, which shows a balance of £57,748. 9s. 1d. of net profits, making, with the amount brought forward from last year, a disposable balance of £62,036. 6s. 8d. Out of this we recommend a dividend of 10s. a share, making the distribution 10 per cent. for the year, and leaving £41,236. 6s. 8d. to be carried forward. The telegraph and electrical departments we have nothing special to report upon I think I informed you at the last meeting of the laying of the cables on the West Coast, and that work has been completed in the most satisfactory way. Our steamers have been partially employed. As regards the premises purchased in Liverpool, that is in consequence of the lease expiring; and in the interest of the Company we thought it better, to prevent any further interruption to the business, to purchase the freehold of the adjoining premises. The extension of the London warehouses is a matter which speaks for itself. Our general trading operations show about the same amount as last year. Notwithstanding the adverse circumstances which we have had to contend with, and with which you are all more or less familiar, but which have, I must say, prevented our participating in the general improvement in the trade of the country, our general trading has kept up to its highest point in amount. Now, as regards the strike at Silvertown, for its exciting cause we have not far to seek. The dock movement took place in the vicinity of our works, and affected a number of labourers there. These men were instigated by the clamour of professional agitators, and several irresponsible advisers, who, I think, would tell us now that they have seen their mistake. The demand made upon us by our *employés* for an increase in pay, notwithstanding that their wages were in excess of those paid in the locality, was refused. A combined attack was made upon those workers—who, I am glad to say, were in considerable number—who were inclined to pursue their daily vocations. The attacks upon them gave rise to picketing—that unmanly system—and in effect a reign of terror was set up. This may be traced to the inaction of the police. I have no hesitation in saying so, as in the later stages, when the police adopted more active measures, the whole movement collapsed, and the *employés* returned quietly to their work on the same terms as heretofore. Now, I must refer to our absent friend, the Managing Director, to whose firmness and sound judgment we must attribute this, for us, happy conclusion. Let me say that at considerable personal risk he was ably supported by his sons, by the whole staff of electricians, the clerks, the young men in the counting house, the foremen, a strong force of assistants, including several workmen and workwomen. The works were therefore kept going throughout. I should also say that from the outset Mr. Gray had the entire confidence and support of the whole Board, who were in perfect agreement with him. I should also add that throughout his long and active life it has been his one object and aim to see that those about him—I mean his workpeople—were justly and kindly treated. He remonstrated with the workpeople and reminded them of the terrible consequences which would occur to them, the whole of which have come to pass. We regret his absence: it is the first time we have missed him. He is seeking rest. In his absence his son Mr. Robert Gray will fill his place, and ably. I hope the time is not far distant when the era of strikes may be chronicled, and I have little doubt that what has taken place at Silvertown within the past year will form an important chapter, and I am sure that prominence in it will be given to the part taken by our friend, who is conspicuous by his absence from among us this day. I should not close these remarks without referring to the Persan works, but I will merely say that they have done good service for us. Without detaining you further I will now move:—

"*That the report and accounts now presented be received and adopted, and that a dividend of 5 per cent., or 10s. a share, free of income-tax, payable on and after 15th inst., be now declared.*"

Mr. NEIL BANNATYNE seconded the motion.

Mr. WEBBER said he had not the least doubt that many of the shareholders were well satisfied with the dividend which it was proposed to declare, equal to 10 per cent. per annum; but personally—and he had no doubt that many other shareholders had the same opinion—he was not satisfied to accept it. He had purchased his shares, unfortunately, when they were at a very high premium, and the suggested dividend to him meant only 4 per cent. A similar dividend had been declared, and on that occasion £9,530 was carried forward, whereas now the amount proposed to be carried forward was £41,200. He considered that this was unfair to those shareholders who were in the same position as he was, for it was not, in his opinion, an adequate return from an apparently fairly-earned balance. He could not see why another 5 per cent. should not be declared, and that would leave over £20,000 to be carried forward. He would, therefore, move:—

"*That a further dividend of 5 per cent. be paid to the shareholders, carrying forward a balance of £20,486.*"

Mr. CORNER seconded the motion.

The SOLICITOR (Mr. Hutchins): That is out of order. The shareholders have no power over the dividend except to sanction that which is proposed by the directors.

Mr. WEBBER: Is that according to the Articles of Association?

The SOLICITOR: Certainly.

Mr. WEBBER: Then, when are these things to be brought forward? You might carry forward £100,000 next time.

Mr. C. WILSON asked whether the reason for carrying forward such a large sum on the present occasion was that it was expected that the money would be required in the business.

The SOLICITOR read Clause 93 of the Articles of Association relating to the declaration of dividends.

Mr. WEBBER said he thought it was a most arbitrary clause.

The CHAIRMAN: I think it only reasonable.

Mr. WEBBER: Some of the Articles of Association require altering. As this clause stands, it means that the Directors might next year carry forward £100,000 and pay no dividend to the shareholders. I consider it most unjust to the shareholders who paid such a high price for their shares as I did.

Mr. BLANKLEY inquired whether the Chairman could give a good reason why they carried forward so much.

Mr. McCRAE asked whether the amendment could not be altered, and take the form of requesting the Directors to divide another 5 per cent.

Mr. WEBBER said he would alter his amendment and make it in the following form:—

"*That this meeting request the Directors to declare an additional dividend of 5 per cent.*"

The CHAIRMAN: The amendment proposed by Mr. Webber would have no avail in any case. The answer to the question asked by Mr. Blankley, as to what reason we can give for carrying forward such an amount, is that as a trading concern we find it most advantageous to be in a position to buy the raw material judiciously in any quantity. I may tell you that that is one of the sources of our profit during the past year—the favourable purchases we have made. The competition in business, in the manufactured articles, is such that we have to be very careful in laying in our stock of raw material. I believe I have answered the only question, and I will now ask you to express your opinion as regards the resolution. Having put the motion in the usual way, and there being five dissentients, he said: There is a large number in favour of it, and I declare the resolution to be carried.

Mr. BANNATYNE: With much pleasure I move:—

"*That Mr. Silver and the Hon. Henry Marsham be and they now are re-elected Directors of the Company.*"

It is unnecessary for me to add anything to commend this resolution to your approval. Mr. Silver is well known, I may say, to all of us. He has been intimately connected with, and has been largely interested in, the Company for many years; and he has occupied the chair for four years. His knowledge of the business, his experience in the affairs of the Company, as well as his general mercantile capacity, amply qualify him to occupy the position of Chairman. Mr. Marsham is comparatively a new Director, if he will allow me to say so, but he has proved himself to the satisfaction of his colleagues. He has been a very valuable addition to the Board since he joined it.

Mr. ABRAHAM SCOTT seconded the resolution, observing that he concurred in every word which had been said by the previous speaker.

The resolution was carried unanimously.

The CHAIRMAN: I desire to thank you in my own name, and in that of my colleague. I assure you that if we can apply ourselves more closely than we have done to the work of the Company, you may depend on our doing so. Our interest in the Company, I may say, is very large. We have not, perhaps, paid £18 per share for our shares; but I think, Mr. Webber, that that is a consideration we can scarcely enter into.

On the motion of Mr. TREBLE, seconded by Mr. CORNER, Mr. J. Weise was re-elected auditor of the Company's accounts for the current year, with a fee of 30 guineas.

Prof. B. PRICE then moved the following resolutions:—

"*This meeting declares and hereby places on record its sense of the great and valuable services rendered to the Company during the recent strike at the Silvertown Works in the firm, prudent, and just action of Mr. Matthew Gray, the managing director, and tenders to him its acknowledgments and thanks for these services. Secondly, the meeting also places on record its grateful appreciation of the services rendered to the Company by the chief manager and the heads of the several departments in the works at Silvertown during the strike; it acknowledges and thanks them for their zeal, their courageous and determined conduct, their command of resources in circumstances of the greatest difficulty, and their successful action in carrying on the works during so severe a crisis; the fidelity of these officers and their devotion to the interests of the Company have the warmest gratitude of this meeting. The meeting also desires to thank the electrical and the clerical staffs for their never-failing exertions in all emergencies during the strike. Thirdly, the meeting also desires to express and to place on record its sympathy with those workmen and workwomen who remained steadfast to their employment during the strike, notwithstanding the severe trials they were subjected to, and it gives its warm thanks to these employés for their patience and their perseverance.*"

The crisis they had passed through in the last six months had been, he took it, very important, and one that affected not only their particular Company, but questions between capital and labour in all parts of England. From the accounts and the report submitted to the shareholders that day they could not regard the position of the Company as being in any way unsatisfactory; but what they had had to go through might have been attended with very unfortunate consequences to many, though so far as the Company were concerned the strike had signally failed. The disasters which the strikers had brought on their families had been very great. The services of Mr. Gray and others justified all that he had said of them in his resolutions, and he might state that the difficulties which that gen-

Digitized by Google

tleman had had to experience were rendered all the greater by the illness and subsequent death of one of his sons.

The CHAIRMAN: I claim to have the privilege of seconding these resolutions. The vote is justly due to all concerned. Think for a moment what would have been the consequences had a failure taken place, what a different appearance we should have presented to-day, and what a different effect would have been produced on those I see around me. He then put the motion, which was carried unanimously.

A vote of thanks to the Chairman brought the meeting to a close.

City of London and Southwark Subway Company.

The eleventh ordinary general meeting of the proprietors of this Company was held yesterday at Winchester House, Old Broad-street, Mr. Charles Grey Mott, presiding.

The SECRETARY (Mr. H. H. M. Smith) having read the notice convening the meeting,

The CHAIRMAN said that it was with mingled feelings of regret and satisfaction that he rose to move the adoption of the report and accounts; with feelings of regret because he had again to meet the proprietors with an unopened line, and with feelings of satisfaction because during the past half-year most excellent progress had been made with the works of the line. They would learn from the report a good deal as to the actual works which had been carried out; but he might specially call their attention to the very important work of driving the tunnels through the wet gravel. That had been carried on uninterruptedly during the whole of the past half-year, with the result that one of the tunnels had been completed, and that the other had only about four or five weeks' work to be done before it would touch the clay on the other side of that wet hollow. Anyone who knew what the difficulty of the work had been—how unexampled almost the nature of it had been—would appreciate the importance of having driven the tunnel so steadily and safely as they had done through most difficult strata and making the two ends meet almost exactly. It was exceedingly creditable to the contractors, to the engineers, and the engineers' staff engaged upon the undertaking. The other tunnel had also progressed perfectly safely so far, and he hoped, as he had said, that in the course of four or five weeks would be completed and into the clay on the other side. They had also during the past half-year completed the boiler houses at Stockwell, upon the erection of which great care had been bestowed. These were fitted upon what was known as Livet's principle, which was extremely economical in its working and free from giving annoyance to the surrounding neighbourhood by the emission of smoke. There were in all six boilers, and they were now at work, and there was practically no smoke arising from them. He thought they were to be congratulated on that arrangement, because the boilers were situated in a residential neighbourhood to which a large emission of smoke would be a great nuisance. The engine-house at the same depot was also rapidly approaching completion, and they were now preparing to fix the engines and dynamos in it. The necessary engines and arrangements for working the hydraulic machinery—which, as they knew, were very extensive, there being two large lifts at six stations to be provided for—were being completed. There were also arrangements for the electric light stations and carriages to be carried out. Then they had another piece of tunnel which had been a somewhat difficult work to carry out—that was the inclined road from the Stockwell depôt down to the tunnel, along which the whole of the plant and working stock of the railway will be taken up and down. He was happy to say that that was now almost finished. The fixing of the lifts had now fairly commenced at several of the stations. Of course a great deal of work had to be performed in the preparation of the shafts which were now completed and ready for the lifts. One important consideration for them was the question of the electric power to be used for working the line. To a large extent the nature of their undertaking was entirely new, and the contractors had, to some extent, to feel their way. They had had an experimental electric locomotive and carriages down in the tunnel running between King William-street and Great Dover-street, which was the most difficult part of the line to work because it went under the river. There were inclines, and a sharp curve going into King William-street Station, and it was desirable that experiments should be made on that part of the line. Those experiments had been carried on for six months, with the result that great improvements had been made in the locomotive working the train. A second one was tried yesterday, and he could only say from his own personal experience that it worked most admirably. The result would be that the locomotives would be constructed in every way fitted, he believed, to do the work thoroughly and efficiently. The locomotives were now being built, and would be completed in time for the opening of the line. They would have noticed that the effect of the near completion of their railway had been such as to satisfy many engineers and others of the value of the system which they had adopted, with that some five new companies gave Parliamentary notice for this Session that they were to apply to obtain powers to construct similar lines in different parts of the metropolis. Of those, he believed, for financial reasons, only one, or possibly two, were left. The one that he knew was left was very important. It proposed to run a line from Queen's-road, Bayswater, down Oxford-street, New Oxford-street, High Holborn, Newgate-street, Cheapside, to the Bank, and there to erect a great central station, and thence to run to a junction with our line just after it left King William-street Station. If that Bill were passed—and there seemed to be very little reason to suppose that it would not be, because there could be no practical objection to a line of that description—it would of course be naturally a great feeder to this Company's line. The only difficulty that they had experienced was that the proposed junction was not made at a station, and was made in an unsatisfactory way. But they hoped that some negotiations would take place the result of which would be that a junction could be effected satisfactorily to all concerned. He mentioned this only to show how completely those who were watching the progress of the Company's undertaking were satisfied that it was one which would be of great importance to the metropolis in the future. They knew that the Company had got a peculiar name which did not at all express what their undertaking was intended to be. Parliament, the Board of Trade, and the Stock Exchange had ranked them a railway company, and, therefore, it was thought better to assume that name, and no longer retain one which did not convey the meaning intended. They asked the proprietors on that account to change the title of the Company to the City and South of London Railway. The proposed junction with the Oxford-street line might possibly render it necessary to construct a station close by the terminus of the Brighton and South-Eastern Railway Companies, and they took powers to get the necessary land should they wish to carry it out. They would, however, hear more on the subject when the necessity arose. As regarded the accounts, they spoke pretty clearly as to what had been done in the matter of expenditure in the past half-year. They had power to issue a further sum of £50,000 of Debentures, making £150,000 in all, and of these there were about £30,000, or a little over, not yet taken up, and the Directors were issuing them, as was well known, and he thought very wisely, as terminable Debentures for five years, and they had, under the circumstances, to pay a little extra rate; but they thought this course to be much better than to issue them as permanent Debenture Stock at a high rate. For the time being, as the line was unopened, it was thought better to offer 5 per cent. for terminable Debentures, and so far they had been successful in placing £116,000. They would be glad if any of the shareholders would avail themselves of the rest at that very good rate for five years. As to the date when the line would be completed and opened, he had as much as possible avoided fixing it, because everything they had had to do was new, as well as the appliances connected with the undertaking, and it was extremely difficult to say under such circumstances at what time the contractors would get their work finished. But he hoped that some time before they met again the line would be opened for traffic—possibly in July or August.

Mr. WALTER ROBINSON seconded the motion.

Mr. RENDALL wished to ask whether the supports in the tunnel had been ascertained to be sufficient, and what were the terms on which they stood in relation to the contractor as to the security of the tunnel.

The CHAIRMAN said that Mr. Rendall might make himself perfectly easy on the subject of the supports of the tunnel. The gravel was strong and hard, although full of water. The tunnel itself was surrounded outside by a lining of concrete, and any one who knew the support derived from wet sandy gravel would know that the pressure was perfectly even all round, and that it was as solid and good a foundation as they could have. A great many most important buildings were erected upon a similar foundation. There was not the slightest risk or danger to be apprehended in regard to the completion of the second tunnel. It was merely a matter of time. It was going on in a perfectly safe manner. As regarded the contractors' liability, it was the ordinary liability of maintenance for twelve months after the completion of the work.

The resolution was carried unanimously.

On the motion of the CHAIRMAN, seconded by Mr. ROBINSON, the retiring directors were re-elected, as were also the Auditors, Messrs. Turquand Youngs and Co., on the motion of Mr. HART, seconded by Mr. PECK.

The meeting was then made special, when the Company's Bill in Parliament received the sanction and approval of the proprietors.

A vote of thanks to the Chairman terminated the proceedings.

Chelsea Electricity Supply Company (Limited).

The ordinary annual general meeting of this Company was held on Wednesday at the Central Station, Draycott-place, Sloane-square, Mr. John Irving Courtenay (the Deputy-Chairman) presiding.

The SECRETARY (Mr. S. J. Cluer) read the notice convening the meeting, and the report was taken as read.

The CHAIRMAN: Gentlemen, it is my duty, in the absence of Lord Thurlow, to address some observations to you before I move the adoption of the Directors' report and balance-sheet. You are aware that though the Company was registered some time ago, the present Board of Directors was not constituted, nor was the capital obtained for the construction of the works, until after the passing of the Electric Lighting Act of 1888; but it was necessary to include in the balance-sheet such small outlays as were made by our predecessors in office. The Board of Trade inquiry necessitated a heavy expenditure which was absolutely necessary to incur to defend our position, and again we had to take part in the proceedings before the Committees of the two Houses. The figures are fully given, not only in respect of these matters, but of every detail connected with the capital and working account in our balance-sheet and profit and loss account, and I do not purpose to detain you by a recapitulation of them, but I am prepared to answer any questions upon them, and to give any shareholder such further information as he may require. The whole of the work has been carried out by the Brush Electrical Engineering Company, the Callender's Bitumen Telegraph and Waterproof Company, the Electrical Power Storage Company, and the Electric Construction Corporation. Our central station has been open for the supply of electricity since the second week in April last year, when current was first turned on from the 2,000-light storage battery sub-station at Clabon Mews. Since then the increasing demand for electric light has induced the Directors to open two other similar battery sub-stations in different districts, and the plant for a fourth is in course of erection. We began with eight houses in April. During the summer, as a matter of course, the increase was slow. By the end of September we were supplying 41 houses, or 2,990 lights. By December 31st the number had increased to 93 houses, or 8,730 lights, and

Digitized by Google

we now have on our books 134 houses, or over 10,000 lights. I would point out that one of the advantages of the system is, that it lends itself readily to gradual increase of plant, according to the necessarily gradual increase in the demand, and does not necessitate at starting the large expenditure of capital on buildings and heavy machinery in the first onset, as with direct-running systems, in which a long time may elapse before sufficient work can be found to fully employ the plant. All the electricity which has been produced has been supplied to the consumer direct from the E.P.S storage batteries. The consumer is never under any circumstances in connection with the charging current, and therefore he is not subject to the disagreeable pulsation and inequality in the light often noticeable when it is produced direct from running machinery. Nor is he in any way liable to the inconvenience of sudden total extinction of his light from difficulties or mishaps with boilers, engines, or dynamos. It is an interesting fact that upon the E.P.S. system, when the batteries are being charged, the engines and dynamo-electric machinery are always operating under the conditions of highest efficiency and maximum output. This is proved in practice by the small consumption of coal, which, for every Board of Trade unit actually supplied to the consumer's lamps, has an average of about 11lb. You will be gratified to learn that little or no symptoms of wear are discoverable even on those E.P.S. batteries that have been longest in use, and in no case has a single plate had to be renewed. I wish to call particular attention to this question of depreciation of accumulators, because it is one of the main points urged against their adoption. I have always contended that in practice it would be found that when storage batteries were installed in central stations (where one man can look after several hundred cells with as much ease as he can look after a few in a private installation), better results would be obtained than had almost ever been got before, and experience is now showing this to be a fact. When by the automatic arrangements of Mr. F. King's system the batteries have their proper charge regularly, and are not permitted to be unduly discharged; that is, discharged beyond their capacity—in other words, when the batteries receive ordinary intelligent treatment—their life will be considerably prolonged. I hope after the meeting you will go through the station and examine the cells yourselves. The batteries in this station are all in glass cells, and you can therefore judge for yourselves what excellent condition they are all in, but a still stronger answer is found in the fact that the manufacturers are prepared to supply all the necessary material for the renewal of any plates or portion of the battery that require renewing, at the annual rate of 12 per cent.; but here at Chelsea, where we have engineers who are well acquainted with E.P.S. storage batteries, we have declined this offer of the manufacturers, because we prefer to be our insurers, as we know it will cost us less than that. You will observe the remarkable comparative statement in the report for the first complete quarter ending December 31st, from which it will be seen that in the month of October, for coal, water, wages, &c., the expenditure was £82. 0s. 10d., while the "current" invoiced to customers amounted to £146. 1s. 6d.; for November the cost for the same items was £114. 14s., and the amount invoiced £262. 8s. 2d.; for December the cost was £141. 9s. 6d., and the amount invoiced £405. 12s.; that is, in November for an expenditure of 39 per cent. greater than that in October, the increase in revenue is 79½ per cent. more than in October, or double the increase in expenditure; and in December, for an expenditure of 23¾ per cent. more than in November, the increase in revenue is 54¾ per cent. greater than in November, or considerably more than double the increase in expenditure. We have found, in actual practice, that the cost of producing a Board of Trade unit of electricity was, in October, 4¼d.; in November, 3⅜d.; in December, 2⅜d., and this should be further improved when our system of underground conductors is quite complete. I venture to say that no other company nor any other system now being operated in this country could show similar results, and if there is any such, at any rate I am not aware of it, and I shall wait with interest to learn whether any similar equally satisfactory results have been produced elsewhere. The success which has attended the working of the E.P.S. system at Chelsea is making some of the advocates of other systems rather unhappy: they are greatly exercised in their minds, and have rushed into public meetings and into print; and if the statements attributed to them in the press are a correct version of what they are saying, they certainly show an amazing hardihood of statement in connection with storage batteries. Storage batteries now can be relied on, and can be guaranteed to give 70 per cent. on an average, in practical working on a commercial scale, of the amount of electricity put into the battery, and they ordinarily give more; and I am informed by those who have made a close study of the subject, that the alternating-current system with transformers working over the whole 24 hours will have an average efficiency of not more than half the average efficiency of the storage battery system. I am, of course, fully aware that those who are interested in rival systems, argue that the great drawback to the storage system is the initial cost. But I maintain, the difference in favour of other systems (if any) will disappear if an adequate duplication of apparatus, plant, and buildings is provided. Should even the original cost of the plant for the storage system be a little greater, surely it is better in the first onset to put down apparatus that will give the highly efficient results that I have shown, than to adopt other systems that are less reliable and have higher working expenses, such as is necessitated by the absence in those systems of a storage reserve, and when they have got this reserve plant they are still liable to breakdowns of moving machinery. In other words, I say that the customers of the Chelsea Company are supplied with a better article than can be given by any other system, and at the same price, and there can be no question that the public are beginning to appreciate this. I have felt bound to make these observations in consequence of the public attacks that have been made upon our storage battery system. You will be gratified to learn that though the vestry of the important parish of St. George, Hanover-square, refused to consent to our application for a Provisional Order in 1888-9, they have now, on our being able to show such good work in Chelsea and Kensington, unanimously consented to allow our application to the Board of Trade for a large portion of their parish, in spite of the fact that two other companies have already been granted powers in the same district. We are vigorously pushing our business in Chelsea and Kensington. What we have to do now is to add on houses, and so increase our customers as rapidly as we possibly can; and I think you will agree that, in view of the good progress we have lately made in this respect, there is every reason to expect a large increase during the current year. I am assured by those who are acquainted with our central station, substations and plant, the solid manner in which they have been constructed and laid down, and the efficient way in which they have been working, that we shall have no difficulty in obtaining, at a moderate rate, the debentures necessary to successfully carry on the prosecution of our extensions; and the increasing ratio of income over expenditure, as already shown, is sufficient evidence that the issue of debentures, by enabling us to extend our mains and use our central station to its full capacity, will prove eventually a great benefit to our shareholders. I beg to move the adoption of the Directors' report and statement of accounts.

Mr. NUGENT DANIELL seconded the motion.

Prof. AYRTON stated that the Chairman had said that the cost of producing a Board of Trade unit of electricity had been in October, November, and December respectively 4¼d., 3⅜d., and 2⅜d. He wished to know whether that was for coal only, or what else it included?

A SHAREHOLDER inquired at what rate they expected to get the debentures taken up.

Major-General WEBBER, C.B., drew attention to a map suspended from the wall, and indicated the nature of the system, which he described as essentially what was called a network system, the advantages of which over any other system he pointed out. By their system it did not matter whether the generating station, as in the case of that station, was exactly in the centre of the area which had to be supplied, nor whether the

Digitized by Google

storing stations and pressure points were exactly in the centre of the area they were meant to supply, because, by the network system, if one point had more work to do than another, it was aided by the other points with which it was connected. This was the provision made for keeping the pressure constant within the limits of variation established by the Board of Trade. If, however, as might happen, the estimates made as to the actual supply likely to be required over any area were exceeded in actual practice, the deficiency could be quickly remedied by replacing short lengths of the existing conductors with conductors of a larger size and greater carrying capacity. Not, however, that they had had any serious difficulty, but it was a point which he desired the shareholders to be aware of, because when they came to examine the system, and saw other systems, they would find variations elsewhere in the pressure of 10 or even 15 per cent., whereas in their own case the variation was never more than 4 per cent. He then alluded to the projected extension, and said that the advantage which they claimed was that all the money laid out had been spent in actual *bona fide* work, and that the money which they would have to lay out—which they must lay out to fulfil their statutory obligations—would be put in actual mains, machinery, and cells, which would, directly they began to work, earn revenue.

The CHAIRMAN, in answer to Prof. AYRTON, said that the cost he had mentioned of producing a Board of Trade unit of electricity included all charges except general charges.

Major-General WEBBER, continuing, pointed out that the general charges were more or less of a fixed nature. The statement just made by the Chairman was an extremely favourable one, and he thought it was rather bold of Mr. Courtenay to put it forward, because, though it was perfectly correct, still he (the speaker) thought it might be a little increased in actual practice.

The CHAIRMAN said that probably there would be some controversy respecting what had been stated at the meeting, but they were perfectly prepared to defend anything they had said.

Major-General WEBBER, in reply to Mr. CALLENDER, stated that the central station at which they had assembled was large enough to contain plant to supply 10 storage stations—that was to say, besides the one in which they were now met, nine outlying stations. By the addition of transformer motors at each of those storage stations, which was under contemplation, and which would be carried out as soon as the maximum demand was approached, they could increase the capacity of each storage station by 50 per cent. They had made estimates which showed that two-fifths of the number of lamps installed in a house were, on the average, in use. He might say that the Draycott-place station had a capacity of supplying 75,000 lamps installed. Speaking of lamps, their unit of lighting, which they thought was essentially one that should be adopted for all domestic purposes, was of 8 to 10 candle-power. With the plant that was now installed and under contract to be installed they could supply from the Draycott-place station 35,500 lamps installed.

The CHAIRMAN put the resolution in the usual manner, and it was carried unanimously. Subsequently he proposed the re-election of Major-General Webber and Mr. Daniell as Directors.

Mr. CUNYNGHAME seconded the motion, and referred to the valuable services which Major-General Webber had rendered to the Company in bringing them with dogged obstinacy and perseverance through all their difficulties. Mr. Daniell was known to him personally, and no doubt to other gentlemen present, and he thought the Company were extremely fortunate in having the services of two such gentlemen.

The resolution was carried unanimously, and subsequently the auditors, Messrs. Cooper Brothers, were re-appointed.

The CHAIRMAN next proposed the following resolution:—

"*That the Directors be, and they are hereby, authorised to borrow a sum not exceeding £50,000, and to secure the same by the issue of Debentures in such form, secured in such manner, and issued to such persons on such terms and at such times as the Directors may deem expedient.*"

They were advised by the solicitor that the resolution was strictly in accordance with the Articles of Association, and that what they required to do they could do simply with the permission of the shareholders. Some shareholders might think that the amount asked for was rather a large sum, and he agreed that £50,000 was a large sum, but they had to take into consideration a great many points in connection with the proposal. He wanted in the first place to obtain the power for the debenture capital once for all, and therefore they asked for powers to obtain £50,000. They had, however, no intention of spending any such sum as that, but they did not want by raising a small sum now to have any difficulty about raising any further debentures they might require, which might be the case if they only raised an amount sufficient for their present requirements. He thought they would issue at once about £12,000, but it was suggested to him that it might be £15,000. They certainly intended to push on in Chelsea and to occupy the ground so as to keep everybody else out. He believed that if in the next two years they spent the amount he had mentioned, with such further sums as might be found necessary for the extensions, the shareholders would all be satisfied. With regard to the question that had been asked as to the rate at which they would get the debentures out, he could only state that they would endeavour to obtain the money as cheaply as possible. He was not able to state exactly what the price would be, and the present was not the moment for obtaining the capital required; but still they hoped that in a short time money would be cheaper, and if they succeeded in issuing debentures from time to time as they saw it was to the advantage of the shareholders, he should say it would be a decided benefit to obtain the additional capital by means of debentures instead of by issuing fresh shares.

Sir GEORGE PRESCOTT, Bart., seconded the motion. He stated that, like Mr. Courtenay, he represented a large amount of share capital in the concern, and they would be extremely cautious and careful in not calling up more money than they might require, and he assured them that it would be expended to the best advantage of the Company.

The CHAIRMAN put the resolution, which was carried unanimously.

A vote of thanks to the Chairman, proposed by Mr. CARR-GOMM, a shareholder, and seconded by Mr. KING, also a shareholder, was carried unanimously, and the proceedings terminated.

NEW COMPANIES REGISTERED.

TRENT GAS ENGINE COMPANY (LIMITED).—This Company was registered on the 6th inst., with a capital of £15,000, in £10 shares, to acquire certain letters patent granted to Richard Simon for inventions or improvements in or connected with gas engines, and to carry on the business of gas engine manufacturers, mechanical engineers, and general merchants, adopting therefor an unregistered agreement expressed to be made with the said Richard Simon. The number of Directors is not to be less than two, nor more than four; qualification, 25 shares. The Company in general meeting will determine remuneration.

P. AND W. MACLELLAN (LIMITED).—This Company has been formed with a capital of £300,000, in 15,000 Six per Cent. Cumulative Preference Shares of £10 each and 15,000 ordinary shares of £10 each, to acquire and carry on as a going concern the well-known business of Messrs. P. and W. Maclellan of the Clutha Works, Glasgow, engineers, iron and steel wagon and bridge builders, iron, steel, metal, and timber merchants.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended February 14th amounted to £4,662.

DIRECT SPANISH TELEGRAPH COMPANY.—Subject to audit, the Directors of this Company have decided to recommend the payment of the dividend at the rate of 10 per cent. on the Preference shares and a dividend at the rate of 6 per cent. (free of income tax) upon the ordinary shares, making 5½ per cent. on the ordinary shares for 1889, against 4½ per cent. in 1888, and to carry forward the sum of £846.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended February 14th, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited), were £3,549.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The receipts of this Company for the half-month ended February 15th show an increase of £233 as compared with the corresponding period.

THE NON-CONDUCTOR OF ELECTRICITY.

WAREHOUSE.

VULCANISED FIBRE,

PATENTED.

This new material is supplied in two qualities, Flexible and Hard.

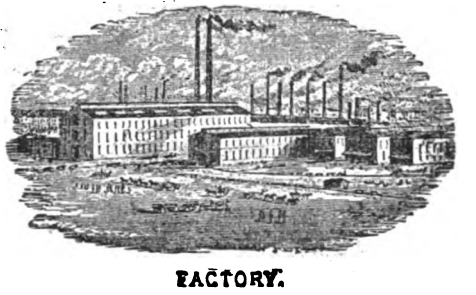
The FLEXIBLE is a substitute for Leather, Rubber, Gutta Percha, &c., and is extensively used by Brass Founders, Axle Makers, Hydraulic, Sanitary, and other Engineers, Pump Makers, Carriage Builders, &c.

It makes the best Hot and Cold Water Packings, and for Axle Washers of all kinds it is unequalled.

The HARD is a substitute for Metals, Hard Wood, Ivory, Vulcanite, Ebonite, &c., and is a good Insulator.

Sold in sheets, 5ft. 6in. by 3ft. 6in., varying in thickness from 1-50in. to 1in.

FLEXIBLE, 2/- per lb.; HARD, 2/3 per lb.



FACTORY.

MOSSES & MITCHELL, 70 Chiswell-st., London, E.C.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 615.—Vol. XXIV. FRIDAY, FEBRUARY 28, 1890. Price Fourpence.

NOTES.

The exhaustive and highly practical Paper read before the Institution of Electrical Engineers by Mr. Esson will be welcomed as a very valuable addition to electrical literature. The empirical rules, founded on experience, which are given for calculating the possible armature load, and the rise of temperature of the dynamo, will be readily used by engineers whose business it is to get at results without stopping to discuss the scientific justification for the method employed. The values of the leakage coefficients of various kinds of dynamos given in Table I. are of much interest, and it is desirable that these results should be confirmed and supplemented by the work of other experimenters. Among the other important points alluded to in the Paper was the pressure on the bearings of dynamos caused by want of magnetic symmetry in the field in which the armature revolves. This pressure was in one case found to be as high as 1,500 pounds The many devices proposed by the author for obtaining magnetic symmetry deserve attentive study.

According to Mr. Esson, the only cause of divergence from perfect reversibility of the dynamo and motor is the influence of the currents in the coils short-circuited by the brushes. These currents increase the field in the motor and diminish it in the dynamo. The number of coils short-circuited by the brushes is, however, small, and the difference between the E.M.F. of the same machine run both as a dynamo and motor is in some cases so large that this explanation is not satisfactory. The difference obtained by Mr. Esson in some of his experiments, shown in Table IV., amounts to as much as 13 per cent. Part of this difference could be accounted for by self-induction, which indirectly causes energy to be absorbed in the short-circuited coils, but the greater part of it would still remain unaccounted for.

A direct system of electric traction which avoids the use of either a conduit or an overhead conductor is certainly a desideratum. Whether Mr. Frank Wynne's plan, a description of which will be found in another column, has solved this problem, experience alone can show; but the first practical application of a system in which contacts (some 590 to the mile), brought into play by electro-magnets, play so prominent a part will be watched with considerable interest by electrical engineers. A somewhat similar system, due to a Mr. Wheless, of Washington, and adapted to series working, was described in these columns some three months ago (*The Electrician*, November 29, 1889). A method of connecting the sections of the central rail successively with the main insulated conductor has also, we believe, been patented by Ayrton and Perry.

In our correspondence column this week attention has been recalled to the interdependence between the life and efficiency of glow-lamps. Several statements made lately about the efficiencies of certain lamps are quite rightly stigmatised as misleading and useless unaccompanied by any reference to the cost of lamp renewals. Our correspondent proposes that the life of lamps should be compared at a standard efficiency, and suggests 3½ watts per candle-power as being suitable. Data connecting the life with the efficiency of glow-lamps are certainly much to be desired. It would not, however, be fair to compare all lamps under the condition of constant efficiency. The working expenses are composed of the cost of the electrical power, together with that of lamp renewals, and the sum is not a minimum for all lamps at the same electrical efficiency.

It will be seen from our American letter this week that the States Postmaster-General is renewing his efforts to bring about at least a partial transfer of the telegraphs to the control of the Government. That the scheme is only of a limited character will probably lessen the support it might otherwise receive, and would not increase its popularity even if accepted. Notwithstanding that the tendency in the United States is towards State, or municipal, control for all public services, the acquisition of the telegraphs is a project of such magnitude that at present we can hardly regard it as within the sphere of practical politics.

The lighting of American towns by electricity under the auspices of the municipal authorities is a much simpler affair, and it will not surprise us if some of the larger cities soon take possession of the local electric lighting companies' works. The friends of the independent companies argue, of course, that the cost of management will be greater, because everybody employed by Government or municipal bodies in America expects to be paid more than he would get in any other service. But this is the very reason why everybody will support the proposal; for in the States, as in the Emerald Isle, from which they are largely recruited, the pet ambition seems to be to become an "official"—that is to say, a person whose duties are lighter, whose wages are higher, and whose self-importance is greater, than those of people whose living depends on their own exertions.

M. BORGMANN describes in a recent number of the *Comptes Rendus* a research on the mechanical action of variable currents, which forms an interesting extension of the experiments of ELIHU THOMSON. Lycopodium powder was spread over the surface of a thin layer of mercury lying in a trough placed above a solenoid, through which an intermittent or alternating current was passed. The frequency used was about 300 per second. The powder was found to be set in motion so as to show the existence of two circular mercury currents flowing in opposite directions, and uniting so as to form a diametral current. The effect was improved by making the layer of mercury as thin as possible. Alternating currents gave better results than intermittent ones, and the presence of an iron core within the solenoid much increased the disturbances. It was not found necessary for the mercury layer to entirely cover the top of the solenoid, as the mercury currents could be observed in isolated drops. By placing pieces of metal over the solenoid the mercury currents were changed, and very curious results were obtained by using a ring formed of three equal sectors of copper, brass and zinc. These interesting experiments are capable of a great deal of extension, and we are glad to see that M. BORGMANN is continuing the research.

DR. LODGE in the current number of *Nature* describes a simple lecture experiment to demonstrate electric resonance. The oscillator consists of a Leyden jar whose inner and outer coatings are connected by means of a rather large loop of wire to two knobs placed near together so as to form a spark gap. The resonator consists of a similar jar whose coatings are connected by a loop of about the same dimensions, but the resistance of which may be adjusted by sliding a copper piece along two parallel wires connected up in circuit. An overflow path is provided for the second jar by means of a strip of tinfoil pasted over its lip and almost long enough to connect the two coatings. By adjusting the position of the slider, the second jar responds every time the first discharges. Prof. LODGE finds that it is not necessary to use long sparks for these experiments, and that, in fact, the vibrations are steadier and more definite with short ones. The extreme simplicity of this experiment will no doubt tempt many to repeat it.

REFERRING to the culvert used by the Pall Mall and St. James's Company, and described by Mr. ADDENBROOKE in our issue of the 14th inst., Mr. ANDERSEN, the patentee, has since pointed out one or two discrepancies, which we correct with pleasure. In the sketches the culvert was drawn with an external flange, which should, however, have been internal. The side of the culvert projects above this internal flange, and the cover fits on it, leaving a space between it and the projection, which is packed with yarn and red and white lead. The external flange is only on the coupling box, which joins two sections together. This coupling box has a projection along its centre, against which the beaded ends of the sections butt, leaving a space which is run with lead, as was described.

WE referred in our issue of January 31st to some important Westinghouse transformer tests, said to have been undertaken at the Massachusetts Institute of Technology, by Mr. W. MARSHALL, under the direction of Prof. C. R. CROSS. Prof. CROSS now writes us that Mr. MARSHALL is entirely unknown to him even by name, and that a student's note-book must have been surreptitiously obtained by him and the figures published. The results given in Mr. MARSHALL'S article form only a small portion of those which have been obtained, converters of various makers having been experimented upon. These tests were, it seems, entirely the work of the students of the Institute, subject only to the general supervision of their instructors, and although Prof. CROSS in no way doubts the substantial accuracy of the figures arrived at, he is not responsible for them. This explanation makes intelligible the omission of all figures relating to efficiency at light-loads to which we called attention at the time.

Tunstall.—The Local Board has decided to support the Order of the Electric Trust Company.

Central London Railway Bill.—This Bill was read a second time in the House of Commons on Tuesday.

International Telegraph Bureau.—M. Frei, Director of Swiss Telegraphs, has been elected Director of the International Telegraph Bureau.

The World's Fair of 1892.—The United States House of Representatives has decided by 157 votes to 107 to make Chicago the scene of the World's Fair in 1892.

Proposed Cable between Tarifa and Ceuta.—The Queen of Spain has signed a decree authorising the Government to present to the Cortes a Bill for laying a cable between Tarifa and Ceuta.

Birmingham Exhibition Awards.—Messrs. Shippey Brothers have been awarded the silver medal diploma for the electric motors exhibited by them at the recent Birmingham Electrical Exhibition.

Croydon.—The Croydon County Council, not having been able to arrange satisfactory terms of purchase with the Croydon Electric Supply Company, have decided to oppose that Company's Order.

Derry.—On Friday last the Derry Corporation held a special meeting to consider their position in relation to electric lighting. It was decided by a majority of 10 to 2 that the Corporation itself should apply for a Provisional Order.

Barnsley.—At the last meeting of the Town Council the Park and Lighting Committee reported that they had approved the conditions of form of proposal to be entered into by companies seeking to supply electricity in the borough.

Maritzburg.—An electric lighting scheme has for some time past caused considerable discussion in this city. The promoters of the scheme wish to be allowed to charge a maximum of 2s. 6d. per unit, about three times the cost of lighting by oil lamps.

Cologne.—The *Elektrotechnisches Echo* announces that the town of Cologne has definitely decided to use alternating currents. The price for private consumers is fixed at ½d. per lamp hour, 500 hours per annum forming the basis of the minimum charge.

The National Electric Light Association Convention.—During the recent meeting of the National Electric Light Association at Kansas City, our enterprising contemporary the *Electrical World* of New York issued a bulletin of the proceedings from its Convention headquarters at Casino Hall, Kansas City.

Appointment Vacant.—The City of London and Southwark Subway Company are prepared to receive applications for the post of general manager of their railway, which will be worked by electric power. Salary to commence at £500 per annum. Applications must be addressed to the Secretary, at the offices, 46, King William-street, not later than Monday, March 10th.

Digitized by Google

A Correction—Problems in the Physics of an Electric Lamp.—On page 394 of our last issue the four lines occurring near Fig. 3 of Dr. Fleming's interesting paper should read:—"We shall illuminate the lamp by a continuous current of electricity, and for brevity's sake speak of that half of the loop of carbon on the side by which the current enters it as the *positive* leg, and the other half of the leg as the *negative* leg," and not as printed.

Rope Gearing.—After having had a certain degree of vogue, says the *Bulletin International de l'Electricité*, rope gearing seems likely to be abandoned, and a return to the discarded belt probable, the reason being that the ropes soon unravel. Although the material is kept in excellent condition at the Halles, the ropes there have already begun to unravel, while the Scellos belts driving the continuous-current machines are still in perfect condition.

Wimbledon.—At the meeting of the Local Board last week, the Electric Lighting Committee laid Mr. Preece's report before the Board. It is proposed to adopt the alternate-current transformer system, and to erect a central station and lay down supply mains at a total cost of £30,000. It is estimated that 350 32 candle-power lamps will replace the 500 oil lamps at present in use. The matter will be further considered at the next meeting of the Board.

Eastern Extension, Australasia, and China Telegraph Company (Limited).—Notice is given that, in pursuance of the conditions upon which the issue of the Five per Cent. Debentures (1880) was made, the sixth and final drawing for payment of these debentures—125 in number—will take place in the presence of a Notary Public, on Monday, March 10th, at 11:30 a.m., at the offices of the company, Winchester House, 50, Old Broad-street, E.C.

Electric Light at Sao Paulo, Brazil.—Rio advices of February 3rd state that the new electric light company of São Paulo has presented a proposal to the Governor for the public and private lighting of that city, assuming the contract with the gas company to be at an end. The prices asked are 15 reis per hour for a 10-candle power incandescent street lamp and 500 reis (about 1s.) per hour for a 500-candle power arc light. Private lighting will be charged 25 per cent. additional.

Institution of Electrical Engineers.—The students of the Institution met last Friday at The Sanctuary, Mr. W. M. Mordey in the chair. A discussion was held on Mr. Swinburne's Paper on the "Theory of Armature Reactions in Dynamos and Motors," in which the Chairman, Messrs. Barton, Walker, Horn, Muir, Childs, and Müller took part. A vote of thanks to the Chairman terminated the proceedings. At the next students' meeting, to be held March 7th, Mr. H. Walker will read a Paper on "Ship Lighting."

Postal Telegraph Balance-Sheet.—A Parliamentary Paper issued yesterday gives an account of the amount received and expended on account of the telegraph service for year ended March 31st last. The gross amount received by the Post Office in respect of telegraphic messages, private wire rentals, special wire rentals, &c., was £2,310,327, the net amount being £2,129,965. The expenditure on account of salaries, rent, and maintenance of telegraphs was £1,969,323, and the balance to meet interest on stock and the redemption of the debt, after paying other expenses, was £88,003. 17s. 9½d.

Reply-Paid Telegrams.—On March 1st, the regulation under which the value of a reply-paid voucher has hitherto been refunded to any person producing the voucher within two months of its date of issue, will be cancelled. In future the value of a reply-paid voucher will only be refunded to the sender of the original telegram, *i.e.*, the person who prepaid the reply. The sender must make application to the Secretary, General Post Office, London, Dublin, or Edinburgh, as the case may be, within two months of the date on which the voucher was issued. The voucher must be produced when the application for the return of the amount is made.

The County Council Testing Station.—At the last meeting of the County Council the Highways Committee reported that they had proceeded further upon the resolution of the Council authorising them to obtain premises suitable for an electric testing station, and they recommended that the Corporate Property Committee be authorised to transfer to the Highways Committee the houses, Nos. 42 and 43, Cranbourn-street, to be used as an electric testing station, and that the Highways Committee be authorised to carry out the works necessary for adapting the premises and to obtain a gas engine and a dynamo for the station at a total estimated cost of about £1,050. This was agreed to.

Undergound Main Systems.—A valued correspondent has supplied the following data omitted from the list published on p. 392 of our last issue:—

Town.	Company and System.	Underground Mains.
Newcastle-on-Tyne	Newcastle and District Electric Lighting Company; alternating, 1,000 volts.	Highest quality of India-rubber (vulcanised) insulation. Cables drawn into cast-iron pipes, with cast-iron junction boxes. All joints vulcanised *in situ* after being made.
„	Newcastle-on-Tyne Electric Supply Company; alternating, 2,000 volts.	Concentric cables drawn into iron pipes, brick junction boxes.

Local Authorities and the Supply of Electricity.—At the last meeting of the Balloon Society of Great Britain Mr. George Offor delivered a lecture on "The Supply of Electricity," referring especially to the action of the local authorities with regard to electrical supply companies seeking Provisional Orders. At the close of the lecture the following resolution was put to the meeting and carried:—"That this meeting urges the Board of Trade to protect the interests of companies prepared to supply electricity from the opposition of local authorities who are unable to prove to the satisfaction of the Board of Trade that their opposition is justified by the special circumstances of the case."

Electric Lighting of the Houses of Parliament.—The first step towards the entire lighting of the Houses of Parliament by electricity was completed, ready for the opening of Parliament on the 11th inst., by the Westminster Electric Supply Corporation. The wiring and fittings inside the building have been carried out from the designs and under the supervision of Mr. Prim, the engineer to the Houses of Parliament, and the effect of the new light, more particularly in St. Stephen's Hall, is most striking.—With reference to a recent paragraph as to the appointment of Mr. Gordon as engineer to this company, we understand that Mr. Gordon has only received the ordinary retainer, and that the chief executive engineer is Prof. Kennedy, F.R.S.

The Electric Light at the Haymarket Stores.—Addressing the shareholders of the Civil Service Co-operative Society at the annual meeting on Monday evening, Mr. Charles J. Cox said that they had found very great advantage from the use of the electric light. It had enabled them to preserve from damage a larger quantity of stock which they would otherwise have been unable to show in the dark winter days, and they proposed at the first available opportunity to extend the electric light throughout the Society's premises. They believed that any extra expense for the light as compared with gas would be more than compensated for by the saving of damage to the stock. At the present time they had not the available space for the machinery, but he wished the shareholders to know that the directors were not losing sight of the great value to the Society of the electric light.

The Inner Temple Installation.—It will be remembered that the large scheme which was started in connection with the Inner Temple, was summarily stopped, and the excavations were filled in. Since then a modified arrangement was prepared with a view to lighting the public offices and supplementing the existing gas engine plant by the addition of a 20 horse-power nominal boiler, and a Willans engine coupled direct to a slow-speed dynamo. The order for this work was given to Messrs. Drake and Gorham, and it has just been completed under the supervision of Mr. W. H. Preece, the consulting engineer to the Inner Temple. The present arrangement allows of any of the three batteries, or all three together, being charged by either dynamo, and the different lamp circuits can be fed from any of the sources of supply. In the summer months the gas engine plant is used for the short runs necessary, or in the event of a sudden fog the gas engine is run until the steam

Digitized by Google

engine is available. This combination of gas and steam will no doubt be found useful in other cases.

Globular Lightning at Pontevedra.—D. Ernesto Caballero, professor of physics, and director of the electric lighting manufactory in Pontevedra, recently wrote to the authorities of the Madrid Observatory giving details of a remarkable meteorological phenomenon which appeared at 9.15 p.m. on January 2nd. In a clear sky there appeared suddenly a ball of fire of the apparent size of an orange, which, after falling upon the conducting wires stretched across the city, entered the manufactory, struck the apparatus for distributing the light, from which (after raising the armature of a magnetic circuit closer) it struck the dynamo at work. It rebounded twice from the dynamo to the conductor, and from the conductor to the dynamo, then fell and burst with a sharp detonation without leaving any trace of its existence. Outside the building, and at the moment of falling upon the conducting wires, the ball was seen by (among others) the Professor of Natural History, Señor Garcéran, and from various effects observed on the wires during the following day there were undoubted manifestations of its electrical origin.

Electrical Bills in Parliament.—The following Bills have been read a second time in the House of Commons:—The Aberdeen Electric Lighting Bill, the Central London Railway Bill, London Subways and Overhead Wires Bill, London Tramways Bill, Luton Gas Bill, and the Partick, Hillhead and Maryhill Gas and Electricity Bill. Petitions have been presented, praying to be heard against the following Bills:—Central London Railway Bill by the Vestries of Paddington, St. George, Hanover-square, and St. Marylebone, the London County Council, the Mercers' Company, the East London Waterworks Company, and Viscount Portman; the City of London and Southwark Subway Bill by the London County Council; the City of London Electric Lighting Bill by the London Electric Supply Corporation and the London County Council; the Partick, Hillhead and Maryhill Gas and Electricity Bill by the Dalmuir, Kilpatrick and Bowling Gas Company, the County Road Board of the lower ward of Lanark, and the Corporation of Glasgow; The London Subways and Overhead Wires Bill by the Kensington and Knightsbridge Electric Lighting Company, the London, Brighton and South Coast Railway Company, and the Southwark and Vauxhall Water Company; The St. Martin's-in-the-Fields Electric Lighting Bill by the London Electric Supply Corporation (Limited) and the London County Council; The Strand Electric Lighting Bill by the London County Council.

Brighton.—In a report issued on Tuesday, the Lighting Committee state that in consequence of a wish expressed by several members of the Council that a second professional opinion should be taken as to the system to be employed by the Council, Mr. R. E. Crompton had been consulted, and his report fully confirmed the opinion of Mr. Shoolbred that the proper system for Brighton is the low tension recommended by the Committee. A site suitable for a generating centre has been offered to the Corporation by Messrs. Vallance and Catt for the sum of £7,000, and the Committee recommend its acceptance. It is further recommended that Mr. J. N. Shoolbred, C.E., should be appointed electrical engineer to the Corporation, "to design, superintend, control, and be responsible for" the whole work. In addition Mr. Shoolbred is to appoint a clerk of the works at a salary of £3 per week (to be paid by the Corporation), who may afterwards, if the Council deem fit, be appointed to take charge as local electrical engineer. The Committee's report concludes with some extracts from Mr. Shoolbred's proposed specifications and Mr. Crompton's report. The plant is to comprise one Babcock and Wilcox and two Galloway boilers; two 120-kilowatt shunt-wound dynamos, running at 350 revolutions, and coupled direct to 200-horse-power compound non-condensing engines; two 45-kilowatt shunt-wound dynamos, running at 450 revolutions, and coupled direct to 80-horse-power engines; a storage battery, in four sets, capable of discharging at the rate of 800 amperes for five hours. A special meeting of the Town Council is convened for Monday next to discuss the report.

The Magnetic Permeability of Soft Steels.—Some dynamo builders having decided to use cast steel for the field-magnet cores and frames of their machines, M. Georges Henrard recently made some experiments at the Montefiore Institute, Liège, in order to find steels sufficiently permeable to be employed for the purpose. The tests, says *La Lumière Electrique*, were made on specimens of steel made at Angleur of all degrees of hardness. The most permeable were very cheap—all could be cast and welded; and No. 6, which cost 7s. 6d. per cwt., was softer than ordinary commercial wrought iron, the carbon contained being only 0·1 to 0·3 per cent. A specimen of wrought iron No. 4, of very good quality, and a specimen of malleable cast-iron from the Herstal foundry, were tested for comparison; the cast iron was a mixture of grey and white pig, and had been decarbonised by heating with Fe_2O_3. The author states that, with **H** equal to 240 C.-G.-S. units, the value of **B** for the bar of malleable iron was more than 15,000 C.-G.-S.; whereas Dr. Hopkinson, in a work published in 1885, gives 12,408 C.-G.-S. as the maximum induction for the metal with the same field. The permeability of a steel cannot be judged of by its percentage of carbon merely, as small percentages of other elements alter the results greatly. For instance, steel No. 5·5, which should be softer and more permeable than No. 5, gave a poorer result, owing to having a greater percentage of manganese. The following table is compiled from some of M. Henrard's figures:—

Steel.	H	μ	Steel.	H	μ
No. 6	250	100	No. 4	250	76
No. 5·5	250	80	No. 3·5	250	80
No. 5	250	80	No. 3	250	74
No. 4·5	250	86	No. 4 (wrought iron)	250	80

Tempered Copper for Electrical Work.—In a recent number of *The Electrical World*, Mr. G. H. Bliss calls attention to the claims of the Eureka Tempered Copper Company, of North East, Pa. The present process of tempering copper has been devised by Mr. Almer Thomas, and its importance is well understood among electricians. Though no table is as yet at hand showing the results of a large number of electrical measurements upon samples of tempered copper, it has been conclusively demonstrated that the modern tempering process does not injure in the slightest degree the conductivity of the copper. By the Thomas process copper is tempered to almost any degree of hardness. Its tensile strength is easily made four or five times that of pure copper, and much superior to hard-drawn copper. Its utility for overhead electrical conductors, where strength and high conductivity must be had, is superior to that of copper in any other form. By this process the Eureka Tempered Copper Company are able to furnish pure copper castings of any desired dimensions. These castings are tempered when required to any degree of hardness. It is a well-known fact that alloyed copper is quickly attacked by alkali, salt water, and mercury. Pure copper is much less affected, and it is therefore practicable to use tempered copper in the form of castings, sheets, and wire in many places where alloyed copper is not available. "Few of us," says Mr. Bliss, "ever supposed that copper would be used for springs, yet this is practicable." The merits of tempered copper have been quickly recognised by many in the electrical fraternity, and already such companies as the Edison, Thomson-Houston, and Westinghouse are using it to a considerable extent. Its superiority over drop-forged castings for commutators and many purposes is readily apparent. Drop forged castings necessarily have greater electrical resistances than pure copper. Pure copper, properly tempered, when used in commutators, is very durable. Tempered copper, when used for gear wheels for electric motors, is noiseless and lasting. It is next to impossible to break or twist off a tooth in a tempered copper gear wheel. "The uses to which tempered copper can be applied," Mr. Bliss remarks in conclusion, "are multiplying daily, and seem to be held in check only by the considerable cost of the article. To those in the electrical profession who have not given the subject attention, it is worthy of early consideration. No one can investigate it without being convinced that its extended use will greatly increase the efficiency, reliability, and durability in every branch of electrical science."

MAGNETISM IN IRON AND OTHER METALS.*—VII.

BY PROF. J. A. EWING, F.R.S.

(*Continued from page 391.*)

§ 40. **Magnetometric Method** (*continued*).—Another position for the specimen to be magnetised is shown in Fig. 14. The plane of the sketch is vertical. O is the magnetometer, which, when undeflected, points at right angles to the plane of the paper. The bar is fixed behind it, standing vertically with its upper pole at the level of the magnetometer. The deflecting force F_2 is mainly due to the upper pole: its value is—

$$\frac{\pi a^2 I}{O Q^2} - \left(\frac{\pi a^2 I}{O Q^2}\right)\frac{O Q}{O Q'} = \frac{\pi a^2 I}{O Q^2}\left\{1 - \left(\frac{O Q}{O Q'}\right)^3\right\}$$

And since this is equal to $F_1 \tan\theta$, we have

$$I = \frac{O Q^2 F_1 \tan\theta}{\pi a^2\left\{1 - \left(\frac{O Q}{O Q'}\right)^3\right\}}.$$

This arrangement is particularly applicable where we have to deal with a very long cylindrical rod (diameter $2a$). In such a rod the position of the effective poles Q and Q′ is uncertain, and, indeed, varies when the intensity of magnetisation is varied. But the method has this advantage, that a change in the position of Q along the rod produces very little change in its distance from the magnetometer,

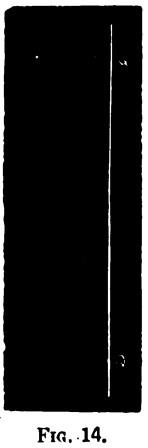

Fig. 14.

and has little effect in altering the deflecting force, while, as to the other pole Q′, its total effect is so small that a movement of it is also without much influence. The best height at which to set the rod will be found by giving it a moderate degree of magnetisation, and finding by trial how high the upper end should stand above the level of the magnetometer to make the deflection a maximum. In this way the position of Q, and therefore of Q′ also, may be found with sufficient accuracy to allow the formula to be applied to a very long cylinder. For brevity, we may distinguish this as the "one-pole" method, seeing that the deflection of the magnetometer is mainly caused by one of the bar's poles.

§ 41. **Details of Magnetometric Method.**—A form of magnetometer, which is exceedingly convenient for observations of this kind, and can be made by anyone at a very trifling cost, is shown in Fig. 15. The suspended "needle" consists of one of the mirrors used in Sir W. Thomson's reflecting galvanometers, with small magnets cemented on the back. The mirror M is hung from a pin, S, at the top of a wooden upright, by a silk fibre three or four inches long. A groove is cut in the upright to allow the fibre to hang free, and at the bottom a round hole, closed in front by a lens, forms a chamber in which the mirror hangs. A glass plate is cemented on the back of the upright to cover the hole and the groove. The upright is fixed to a horizontal plate furnished with three levelling screws. The deflection of the mirror is read in the usual way by means of a lamp and scale.

* All rights are reserved.

In using a mirror magnetometer, the angle through which the needle is deflected may generally be kept so small that no account need be taken of the difference between $\tan\theta$ and θ, and consequently the scale readings may be taken as proportional to the deflecting forces. Thus, if we have a scale 50cm. long, set one metre from the magnetometer, a deflection of the needle amounting to only about 7deg. will make the spot of light travel from the middle to the end of the scale. (It must be remembered that the angular deflection of the mirror is only half that of the beam of light.) Even for this largest deflection the error caused by taking scale divisions instead of tangents is barely a half of one per cent., and for smaller deflections the error is very much less. In such a case, therefore, instead of $\tan\theta$ we may write θ, which is equal to $\frac{\delta}{2D}$, δ being the deflection as measured on the scale, and D the distance of the scale from the mirror expressed in scale divisions.

Fig. 16 illustrates an arrangement for examining the magnetic quality of long thin rods or wires by the "one-pole" variety of the magnetometric method. The specimen is slipped into a tube, A, which is clamped in a vertical position behind the magnetometer B, the distance being adjusted by trial to make the deflection conveniently large. Over the tube a magnetising solenoid is wound, extending a little way above and below the wire core, so that the magnetising force inside may be sensibly uniform, except in so far as it is affected by the ends of the specimen itself. (When only one wire is to be tested, the magnetising solenoid may conveniently enough be wound on the wire itself, instead of on a tube.) Owing to the vertical position of the specimen, it is exposed to the vertical

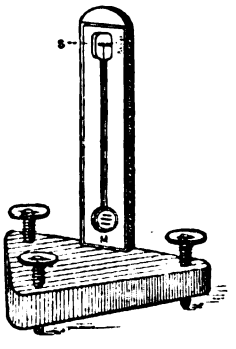

Fig. 15.

component of the earth's magnetic force. For many purposes it is desirable to eliminate this, so that the only force acting along the wire may be that due to the magnetising solenoid. To secure this a second solenoid is wound upon the tube, and through it a constant current is kept up, the strength of which is adjusted (by a method to be described later) until the magnetic force it produces within the tube just balances the earth's vertical force. In the sketch, the single gravity Daniell cell C and the resistance box D give the means of maintaining and regulating this constant current.

In circuit with the main solenoid and behind the specimen is a coil, E, consisting of a few turns of wire wound on a wooden frame which can slide towards or from the magnetometer, its axis passing through the magnetometer at right angles to the undeflected direction of the needle. This "compensating coil," as we shall call it, serves to neutralise the direct action of the magnetising solenoid upon the magnetometer. Its position is adjusted thus: Before putting the specimen to be magnetised into the magnetising solenoid, pass a fairly strong current through the solenoid and the compensating coil, and push the coil backwards or forwards until the magnetometer shows no deflection. The adjustment remains correct for all currents, and its effect is that when the specimen is put in no deduction has to be made from the observed deflection on account of the magnetising solenoid.

We may of course allow for the effect of the solenoid without using a compensating coil, by observing what deflection the solenoid itself produces with a given strength of current when the specimen is removed, and then making a proportional

Digitized by Google

deduction for other currents. The compensating coil, however, has a great advantage over this in point of practical convenience, and has other uses besides, of which examples will be given later.

In each part of the connections the leading wires are twisted together—a very necessary precaution to prevent their acting on the magnetometer.

In examining the permeability of a specimen, a weak magnetising current is first applied, and this is increased step by step or continuously, observations of the current strength being taken along with observations of the magnetometric deflection. A storage battery forms the most convenient source of current; use a low-resistance mirror galvanometer, strongly controlled by a fixed permanent magnet, and test its sensibility by passing a current through it from a gravity Daniell cell; the strength of the current in amperes may be taken as $\frac{1 \cdot 1}{R}$, where R is the total resistance of the circuit in ohms. Care must be taken to set up the galvanometer far enough away from the magnetometer to prevent one from acting on the other.

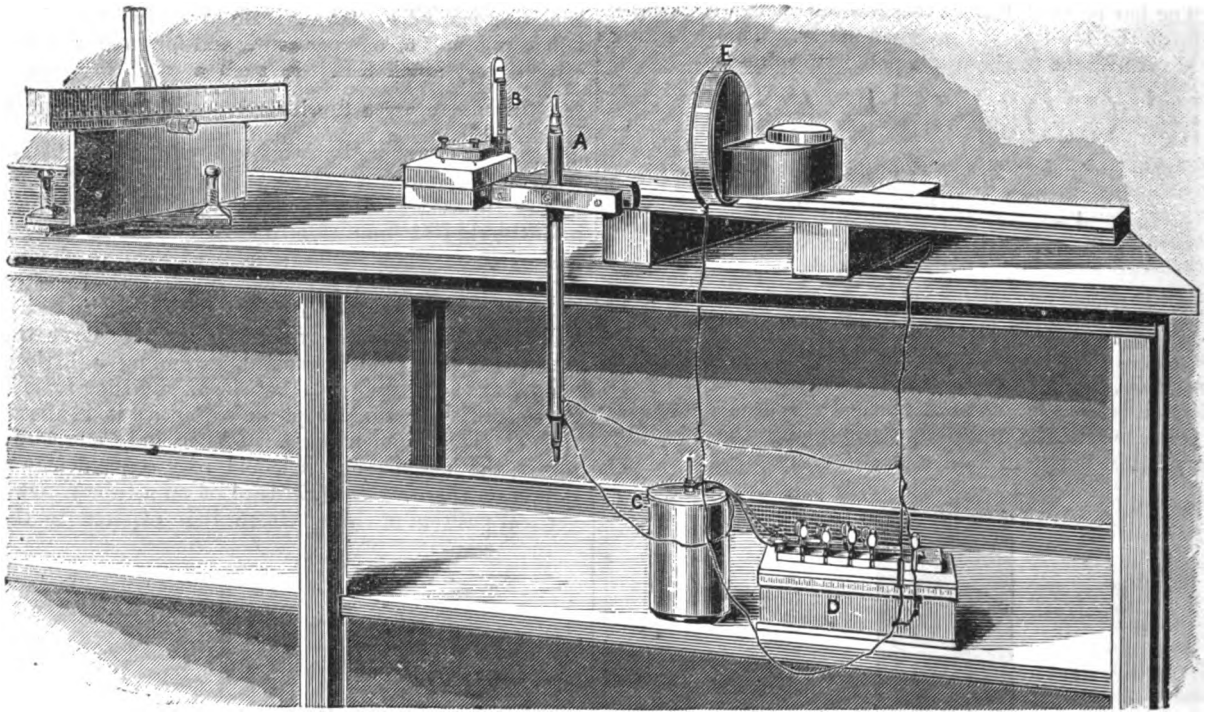

Fig. 16.—Arrangement for Examining the Magnetic Quality of Long Thin Rods.

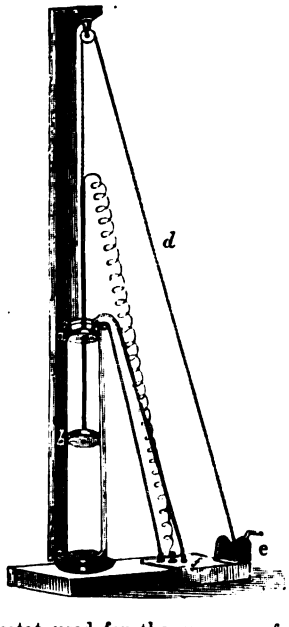

Fig. 17.—Liquid rheostat used for the purpose of continuously altering the strength of the magnetising current.

that is not available, a battery of gravity Daniell's will do well. To observe the current strength, any good form of galvanometer or ampere-meter may be kept in circuit with the magnetising solenoid. A plan which is as good as any is to

In many magnetic experiments it is desirable to have the means of altering the magnetising current continuously instead of by steps, between zero and its highest value. This is conveniently effected by using the liquid rheostat, or potential slide, shown in Fig. 17. A tall glass jar of fairly uniform bore, two inches or so in diameter, is filled with dilute solution of sulphate of zinc. Three blocks of amalgamated zinc, *a*, *b*, and *c*, are fitted in the jar, one lying at the bottom, another fixed at the top, and the third hung between them so that

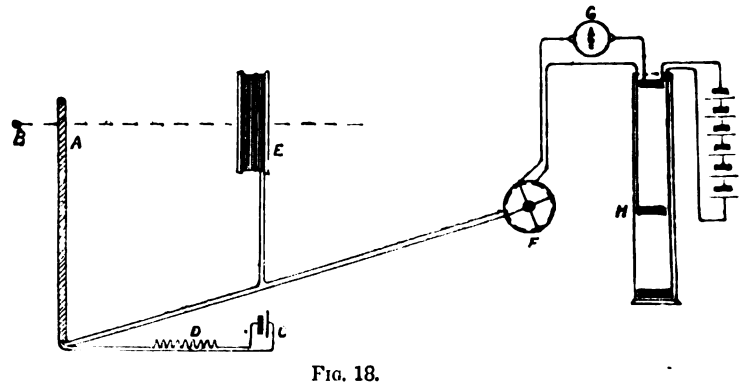

Fig. 18.

it may be raised or lowered by the cord *d* which passes over a pulley above to the little winch at *e*. The blocks are connected to three terminals at *f*, insulated wires being led up through the liquid from the middle and lower blocks. The battery is connected to *a* and *c*, so that the liquid column forms a shunt to it, and a part of its E.M.F. is taken off to produce current in the magnetising solenoid by connecting the ends of the solenoid to one of the fixed and one of the moving blocks, say *a* and *b*. Thus, when *b* is raised into contact with *a* no current passes through the solenoid, and when *b* is

Digitized by Google

gradually lowered the current increases, reaching its highest value when *b* touches *c*. With this slide it is easy to adjust the current to any intermediate value, and to keep it constant for as long as may be wished.

Fig. 18 is a general diagram of the connections. The letters A, B, C, D and E refer to the same parts as in Fig. 16. F is a revolving commutator, G a galvanometer for measuring the magnetising current, and H is the slide described above.

§ 42. **Demagnetising by Reversals.**—The liquid slide gives a handy means of performing a process which is resorted to when we wish to rid the specimen of any initial magnetism it may possess, or to wipe out the residual effects of previous operations. The process of "demagnetising by reversals" consists in applying a numerous series of magnetic forces alternating in direction, and gradually diminishing to zero. A commutator or rapid reversing key is inserted either between the battery and the slide or between the slide and the magnetising solenoid. Working it rapidly with one hand, and turning the winch-handle of Fig. 17 very slowly with the other, the operator applies a long series of alternating magnetising currents, each a very little weaker than the one before it, and the result is, when the process is carefully conducted, to remove all trace of residual magnetism, provided the strongest current of the series is at least as strong as the current by which the piece had been previously magnetised.

§ 43. **Adjustment of the Current Required to Balance the Vertical Component of the Earth's Field.**—The operation of demagnetising by reversals will not be completely successful unless the earth's vertical force is very exactly balanced, otherwise there will be a one-sidedness in the alternate opposite magnetic forces, which will show itself by leaving a persistent residue of magnetism in one direction or the other, the direction depending on whether the constant current which is applied to balance the earth's force is too strong or too weak. This affords an excellent criterion by which we may adjust the current. It has to be strengthened or weakened until, when the process of demagnetising by reversals is performed, the demagnetisation is complete. The more susceptible the material within the solenoid the more sensitive is the test, and it is well to keep at hand, for the purpose of adjusting the current in this way, a core of soft annealed iron, which may be slipped into the solenoid when the test is to be made. In order to increase the sensibility further, when a fine adjustment is required, the solenoid should be set a good deal closer to the magnetometer than it is set when we are afterwards measuring the magnetism of a wire or rod within it.

(To be continued.)

PROBLEMS IN THE PHYSICS OF AN ELECTRIC LAMP.*

BY PROF. J. A. FLEMING, M.A., D.SC., M.R.I.

(Concluded from page 395.)

At this stage it will perhaps be most convenient to outline briefly the beginnings of a theory proposed to reconcile these facts, and leave you to judge how far the subsequent experiments confirm this hypothesis. The theory very briefly is as follows:—From all parts of the incandescent carbon loop, but chiefly from the negative leg, carbon molecules are being projected which carry with them, or are charged with, negative electricity. I will in a few moments make a suggestion to you which may point to a possible hypothesis on the manner in which the molecules acquire this negative charge. Supposing this, however, to be the case, and that the bulb is filled with these negatively-charged molecules, what would be the result of introducing into their midst a conductor such as this middle metal plate which is charged positively? Obviously, they would all be attracted to it and discharge against it. Suppose the positive charge of this conductor to be continually renewed, and the negatively-charged molecules continually supplied, which conditions can be obtained by connecting the middle plate to the positive electrode of the lamp, the obvious result will be to produce a current of electricity flowing through the wire or galvanometer, by means of which this middle plate is connected to the positive electrode of the lamp. If, however, the middle plate is connected to the negative electrode of the lamp, the negatively-charged molecules can give up no charge to it, and produce no current in the interpolated galvanometer. We see that on this assumption the effect must necessarily be diminished by any arrangement which prevents these negatively-charged molecules from being shot off the negative leg or from striking against the middle plate. Another obvious corollary from this theory is that the "Edison effect" should be annihilated if the metal collecting plate is placed at a distance from the negative leg much greater than the mean free path of the molecules.

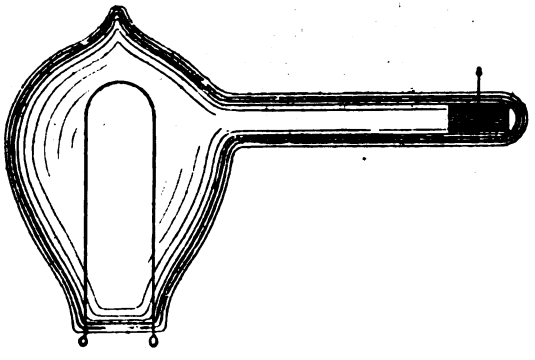

FIG. 8.—Collecting plate placed at end of tube, 18in. in length, opening out of bulb.

Here are some experiments which confirm this deduction. In this bulb (Fig. 8) the metal collecting plate, which is to be connected through the galvanometer with the positive terminal of the lamp, is placed at the end of a long tube opening out of and forming part of the bulb. We find the "Edison effect" is entirely absent, and that the galvanometer current is zero.

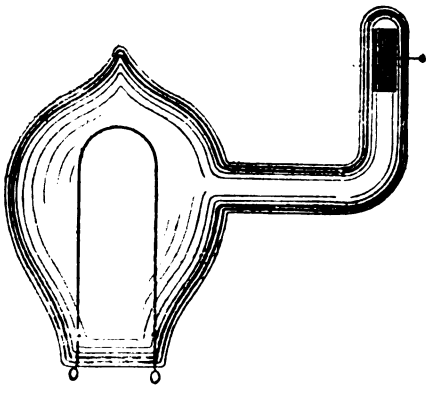

FIG. 9.—Collecting plate placed at end of elbow tube opening out of bulb.

We have, as it were, placed our target at such a distance that the longest range molecular bullets cannot hit it, or, at least, but very very few of them do so. Here again is a lamp in which the plate is placed at the extremity of a tube opening out of the bulb, but bent at right angles (Fig. 9). We find in this case, as first discovered by Mr. Preece, that there is no "Edison effect." Our molecular marksman cannot shoot round a corner. None of the negatively charged molecules can reach the plate, although that plate is placed at a distance not greater than would suffice to produce the effect if the bend were straightened out. Following out our hypothesis into its consequences would lead us to conclude that the material of which the plate is made is without influence on the result, and this is found to be the case. Many of the foregoing facts were established by Mr. Preece as far back as 1885, and I have myself abundantly confirmed his results.

* A discourse delivered at the Royal Institution on Friday evening, February 14, 1890.

Digitized by Google

We should expect also to find that the larger we make our plate, and the nearer we bring it to the negative leg of the carbon, the greater will be the current produced in a circuit connecting this plate to the positive terminal of the lamp. I have before me a lamp with a large plate placed very near the negative leg of the carbon of a lamp, and we find that we can collect enough current from these molecular charges to work a telegraph relay and ring an electric bell. The current which is now working this relay is made up of the charges collected by the plate from the negatively-charged carbon molecules which are projected against it from the negative leg, across the highly perfect vacuum. I have tried experiments with lamps in which the collecting plate is placed in all kinds of positions, and has various forms, some of which are here, and are represented in the diagrams before you; but the result may all be summed up by saying that the greatest effects are produced when the collecting plate is as near as possible to the base of the negative end of the loops, and, as far as possible, encloses, without touching, the carbon conductor. Time will not permit me to make more than a passing reference to the fact that the magnitude of the current flowing through the galvanometer when connected between the middle plate and the positive terminal of the lamp often "jumps" from a low to a high value, or *vice versâ*, in a remarkable manner, and that this sudden change in the current can be produced by bringing strong magnets near the outside of the bulb.

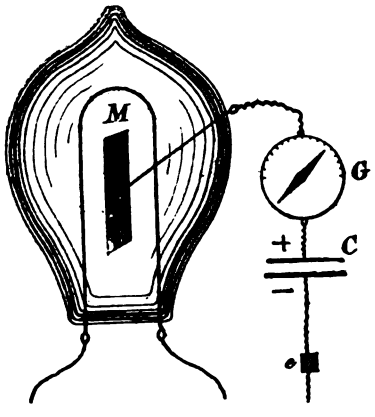

FIG. 10.—Charged condenser *C* discharged by middle plate *M*, when the positively charged side of condenser is in connection with the plate and other side to earth *e*.

Let us now follow out into some other consequences this hypothesis that the interior of the bulb of a glow lamp when in action is populated by flying crowds of carbon atoms all carrying a negative charge of electricity. Suppose we connect our middle collecting plate with some external reservoir of electric energy, such as a Leyden jar, or with a condenser equivalent in capacity to many hundreds of Leyden jars, and let the side of the condenser which is charged positively be first placed in connection through a galvanometer with the middle plate (*see* Fig. 10), whilst the negative side is placed in connection with the earth. Here is a condenser of two microfarads capacity so charged and connected. Note what happens when I complete the circuit and illuminate the lamp by passing the current through its filament. The condenser is at once discharged. If, however, we repeat the same experiment with the sole difference that the negatively charged side of the condenser is in connection with the middle plate then there is no discharge. The experimental results may be regarded from another point of view. In order that the condenser may be discharged as in the first case it is essential that the negatively charged side of the condenser shall be in connection with some part of the circuit of the incandescent carbon loop. This experiment with the condenser discharged by the lamp may be then looked upon as an arrangement in which the plates of a charged condenser are connected respectively to an incandescent carbon loop and to a cool metal plate, both being enclosed in a highly vacuous space, and it appears that when the incandescent conductor is the negative electrode of this arrangement the discharge takes place, but not when the cooler metal plate is the negative electrode of the charged condenser. The negative charge of the condenser can be carried across the vacuous space from the hot carbon to the colder metal plate, but not in the reverse direction.

This experimental result led me to examine the condition of the vacuous space between the middle metal plate and the negative leg of the carbon loop in the case of the lamp employed in our first experiment. Let us return for a moment to that lamp. I join the galvanometer between the middle plate and the negative terminal of the lamp, and find, as before, no indication of a current. The metal plate and the negative terminal of the lamp are at the same electrical potential. In the circuit of the galvanometer we will insert a single galvanic cell having an electromotive force of rather over one volt. In the first place let that cell be so inserted that its negative pole is in connection with the middle plate, and its positive pole in connection through the galvanometer with the negative terminal of the lamp (*see* Fig. 11). Regarding the circuit of that cell alone, we find that it consists of the cell itself, the galvanometer wire, and that half-inch of highly vacuous space between the hot carbon conducter and the middle plate. In that circuit the cell cannot send any sensible current at all, as it is at the present moment connected up. But if we reverse the direction of the cell so that its positive pole is in connection with the middle plate, the galvanometer at once gives indications of a very sensible current. This highly vacuous space, lying between the middle metal plate on

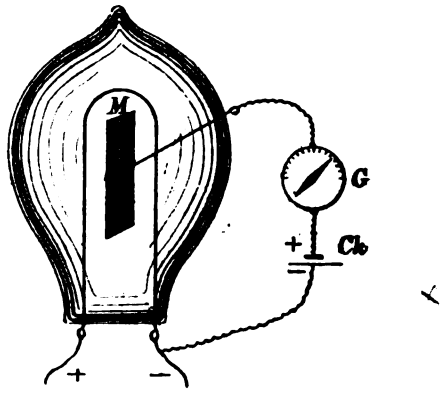

FIG. 11.—Current from Clark cell *Ck* being sent across vacuous space between negative leg of carbon and middle plate *M*. Positive pole of cell in connection with plate *M* through galvanometer *G*.

the one hand and the incandescent carbon on the other, possesses a kind of unilateral conductivity, in that it will allow the current from a single galvanic cell to pass one way but not the other. It is a very old and familiar fact, that in order to send a current from a battery through a highly rarefied gas by means of metal electrodes, the electromotive force of the battery must exceed a certain value. Here, however, we have indication that if the negative electrode by which that current seeks to enter the vacuous space is made incandescent the current will pass at a very much lower electromotive force than if the electrode is not so heated.

A little consideration of the foregoing experiments led to the conclusion that in the original experiment, as devised by Mr. Edison, if we could by any means render the middle plate very hot, we should get a current flowing through a galvanometer when it is connected between the middle plate and the negative electrode of the carbon. This experiment can be tried in the manner now to be shown. Here is a bulb (Fig. 12) having in it two carbon loops; one of these is of ordinary size and will be rendered incandescent by the current from the mains. The other loop is very small, and will be heated by a well-insulated secondary battery. This smaller incandescent loop shall be employed just as if it were a middle metal plate. It is, in fact, simply an incandescent middle conductor. On repeating the typical experiment with this arrangement we find that the galvanometer indicates a current when connected between the middle loop and either the positive *or* the negative terminal of the main carbon. I have little doubt but that if we could render the platinum plate in our first-used lamp incandescent

Digitized by Google

by concentrating on it from outside a powerful beam of radiant heat we should get the same result.

A similar set of results can be arrived at by experiments with a bulb constructed like an ordinary vacuum tube, and having small carbon loops at each end instead of the usual platinum or aluminium wires. Such a tube is now before you (*see* Fig. 13), and will not allow the current from a few cells of a secondary battery to pass through it when the carbon loops are cold. If, however, by means of well insulated secondary batteries we render both of the carbon loop electrodes highly incandescent, a single cell of a battery is sufficient to pass a very considerable current across that vacuous space provided the resistance of the rest of the circuit is not large. We may embrace the foregoing facts by saying that if the electrodes, but especially the negative electrode, which form the means of

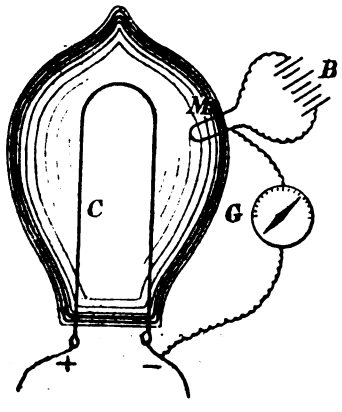

FIG. 12.—Experiment showing that when the "middle plate" is a carbon loop rendered incandescent by insulated battery *B*, a current of negative electricity flows from *M* to the positive leg of main carbon *C* across the vacuum.

ingress and egress of a current into a vacuous space are capable of being rendered highly incandescent, and if at that high temperature they are made to differ in electrical potential by the application of a very small electromotive force, we may get under these circumstances a very sensible current through the rarefied gas. If the electrodes are cold a very much higher electromotive force will be necessary to begin the discharge or current through the space. These facts have been made the subject of elaborate investigation by Hittorf and Goldstein, and more recently by Elster and Geitel. It is to Hittorf that I believe we are indebted for the discovery of the fact that by heating the negative electrode we greatly reduce the apparent resistance of a vacuum.

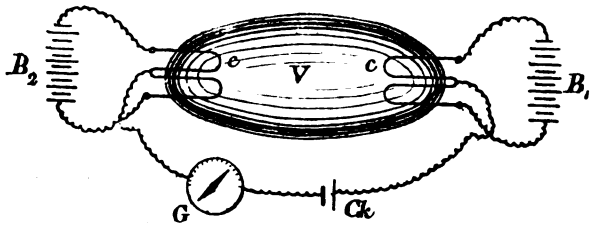

FIG. 13.—Vacuum tube having carbon loop electrodes, *c c*, at each end rendered incandescent by insulated batteries, B_1 B_2, showing current from Clark cell, *Ck*, passing through the high vacuum when the electrodes are incandescent.

Permit me now to pave the way by some other experiments for a little more detailed outline of the manner in which I shall venture to suggest these negative molecular charges are bestowed. This is really the important matter to examine. In seeking for some probable explanation of the manner in which these wandering molecules of carbon in the glow-lamp bulb obtain their negative charges, I fall back for assistance upon some facts discovered by the late Prof. Guthrie. He showed some years ago new experiments on the relative powers of incandescent bodies for retaining positive and negative charges. One of the facts he brought forward* was that a bright red-hot iron ball, well insulated, could be charged negatively, but could not retain for an instant a positive charge. He showed this fact in a way which it is very easy to repeat as a lecture experiment. Here is a gold-leaf electroscope, to which we will impart a positive charge of electricity, and project the image of its divergent leaves on the screen. A poker the tip of which has been made brightly red hot is placed so that its incandescent end is about an inch from the knob of the electroscope. No discharge takes place. Discharging the electroscope with my finger, I give it a small charge of negative electricity, and replace the poker in the same position. The gold leaves instantly collapse. Bear in mind that the extremity of the poker when brought in contiguity to the knob of the charged electroscope becomes charged by induction with a charge of the opposite sign to that of the charge of the electroscope, and you will at once see that this experiment confirms Prof. Guthrie's statement, for the negatively-charged electroscope induces a positive charge on the incandescent iron, and this charge cannot be retained. If the induced charge on the poker is a negative charge it is retained, and hence the positively-charged electroscope is not discharged, but the negatively-charged electroscope at once loses its charge. Pass in imagination from iron balls to carbon molecules. We may ask whether it is a legitimate assumption to suppose the same fact to hold good for them, and that a hot carbon molecule or small carbon mass just detached from an incandescent surface behaves in the same way and has a greater grip for negative than for positive charge? If this can possibly be assumed, we can complete our hypothesis as follows:—Consider a carbon molecule or small congerie of molecules just set free by the high temperature from the negative leg of the incandescent carbon horseshoe. This small carbon mass finds itself in the electrostatic field between the branches of the incandescent carbon conductor (*see* Fig. 14). It

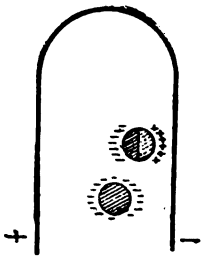

FIG. 14.—Rough diagram illustrating a theory of the manner in which projected carbon molecules may acquire a negative charge.

is acted upon inductively, and if it behaves like the hot iron ball in Prof. Guthrie's experiment it loses its positive charge. The molecule then being charged negatively is repelled along the lines of electric force against the positive leg. The forces moving it are electric forces, and the repetition of this action would cause a torrent of negatively-charged molecules to pour across from the negative to the positive side of the carbon horseshoe. If we place a metal plate in their path, which is in conducting connection with the positive electrode of the lamp carbon, the negatively-charged molecules will discharge themselves against it. A plate so placed may catch more or less of this stream of charged molecules which pour across between the heels of the carbon loop. There are many extraordinary facts, which as yet I have been able only imperfectly to explore, which relate to the sudden changes in the direction of the principal stream of these charged molecules, and to their guidance under the influence of magnetic forces. The above rough sketch of a theory must be taken for no more than it is worth, viz., as a working hypothesis to suggest further experiments.

These experiments with incandescence lamps have prepared the way for me to exhibit to you some curious facts with respect to the electric arc, and which are analogous to those which we have passed in review. If a good electric arc is formed in the usual way, and if a third insulated carbon held at right angles to the other two is placed so that its tip just dips into the arc

* "On a New Relation between Electricity and Heat," *Phil Mag.*, Vo XLV., p. 308. 1873.

Digitized by Google

(*see* Fig. 15), we can show a similar series of experiments. It is rather more under control if we cause the arc to be projected against the third carbon by means of a magnet. I have now formed on the screen an image of the carbon poles and the arc between them in the usual way. Placing a magnet at the back of the arc, I cause the flame of the arc to be deflected laterally and to blow against a third insulated carbon held in it. There are three insulated wires attached respectively to the positive and to the negative carbons of the arc, and to the third or insulated carbon, the end of which dips into the flame of the arc projected by the magnet. On starting the arc this third carbon is instantly brought down to the same electrical potential as the negative carbon of the arc, and if I connect this galvanometer in between the negative carbon and the third or insulated carbon I get, as you see, no indication of a current. Let me, however, change the connections and insert the circuit of my galvanometer in between the positive carbon of the arc and the middle carbon, and we find evidence, by the violent impulse given to the galvanometer that, there is a strong current flowing through it. The direction of this current is equivalent to a flow of negative electricity from the middle carbon through the galvanometer to the positive carbon of the arc, We have here then the "Edison effect" repeated with the electric arc. So strong is the current flowing in a circuit connecting the middle carbon with the positive carbon that I can, as you see, ring an electric bell and light a small incandescent lamp when these electric-current detectors are placed in connection with the positive and middle carbons.

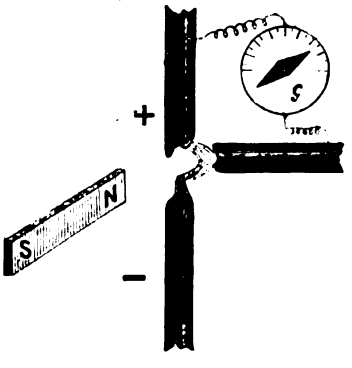

FIG. 15.—Electric arc projected by magnet against a third carbon, and showing strong electric current flowing through a galvanometer, *G*, connected between the positive and third carbon.

We also find that the flame-like projection of the arc between the negative carbon possesses a unilateral conductivity. I join this small secondary battery of fifteen cells in series with the galvanometer, and connect the two between the middle carbon and the negative carbon of the arc. Just as in the analogous experiment with the incandescent lamp, we find we can send negative electricity along the flame of the arc one way but not the other. The secondary battery causes the galvanometer to indicate a current flowing through it when its negative pole is in connection with the negative carbon of the arc (*see* Fig. 16), but not when its positive pole is in connection with the negative carbon. On examining the third or middle carbon after it has been employed in this way for some time we find that its extremity is cratered out and converted into graphite, just as if it had been employed as the positive carbon in forming an electric arc. Time forbids me to indulge in any but the briefest remarks on these experiments; but one suggestion may be made, and that is that they seem to indicate that the chief movement of carbon molecules in the electric arc is *from* the negative *to* the positive carbon. The idea suggests itself that, after all, the cratering out of the positive carbon of the arc may be due to a sand-blast-like action of this torrent of negatively-charged molecules which are projected from the negative carbon. If we employ a soft iron rod as our lateral pole, we find that, after enduring for some time the projection of the arc against it, it is converted at the extremity into *steel*.

Into the fuller discussion as to the molecular actions going on in the arc, the source and nature of that which has been called the counter-electromotive force of the arc, and the causes contributing to produce unsteadiness and hissing in the arc, I fear that I shall not be able to enter, but will content myself with the exhibition of one last experiment, which will show you that a high vacuum, or, indeed, any vacuum, is not necessary for the production of the "Edison effect." Here is a carbon-horseshoe-shaped conductor, not enclosed in any receiver (see Fig. 17). Close to the negative leg or branch, yet not touching it, we have adjusted a little metal plate. The sensitive galvanometer is connected between this metal plate and the base of the other or positive leg of this carbon arch. On sending a current through the carbon sufficient to bring it to bright incandescence, the galvanometer gives indications of a current flowing through it, and

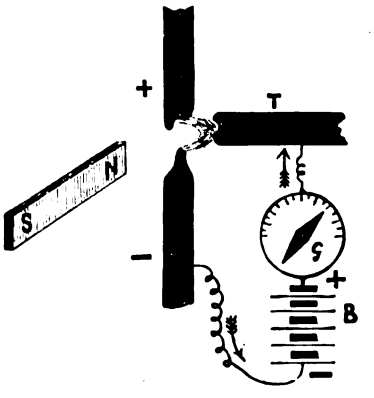

FIG. 16.—Galvanometer *G* and battery *B* inserted in series between negative carbon of electric arc and a third carbon to show unilateral conductivity of the arc between the negative and third carbons.

as long as the carbon endures, which is not, however, for many seconds, there is a current of electricity through it equivalent to a flow of negative electricity from the plate through the galvanometer to the positive electrode of the carbon. The interposition of a thin sheet of mica between the metal plate and the negative leg of the carbon loop entirely destroys the galvanometer current.*

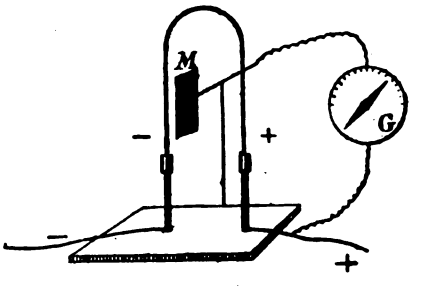

FIG. 17.—"Edison effect" Experiment shown with carbon in open air.

These experiments and brief expositions cover a very small portion of the ground which is properly included within the limits of my subject. Such fragments of it as we have been able to explore to-night will have made it clear that it is a region abounding in interesting facts and problems in molecular physics. The glow lamp and the electric arc have revolutionised our methods of artificial lighting, but they present themselves also as subjects of scientific study, by no means yet exhausted of all that they have to teach.

THE TELEGRAPH IN DENMARK.

BY CARL V. HANSEN.

Prior to the introduction of the electric telegraph the semaphore system was in vogue in Denmark as elsewhere, and to a certain extent met the demand for rapid communication. After the discovery of electro-magnetism had led to practical results, the countrymen of Hans Christian Oersted were among the first to introduce the electric telegraph as a rapid means of communication. In 1839 a short line was erected in Copenhagen. It was, however, not until 1850, after the war with Germany, that the Government commenced to collect information on the subject from

* This last experiment is due to my assistant, Mr. A. H. Bate.

Digitized by Google

countries where the system was already in active use. A Bill relating to the erection of electric telegraphs passed the Danish Parliament in 1852, and it was resolved that the construction and working of the line should be entrusted to an officer of the Royal Engineers who had acquainted himself with the subject during a stay abroad.

An underground line was commenced between Elsinore and Hamburg, consisting of a copper wire surrounded by a covering of gutta percha, and placed in a leaden tube, but the insulation failing, it was necessary to take the line up again. After surmounting considerable difficulties the line, 240 miles in length, was completed and opened for traffic on February 1, 1854, but broke down temporarily that very day owing to a landslip. On January 1, 1855, a cable was laid across the sound from a point near Elsinore to Helsingborg, establishing communication between Denmark, Sweden, and Norway. The first telegraph lines, both short, in Sweden and Norway, were opened in 1853 and 1854 respectively. Meanwhile, in Denmark the difficulties of maintaining and working a subterranean line increased, and considerable trouble being experienced in despatching even the few messages, about 80 a day, handed in, it was resolved to abandon the underground wire and adopt the overhead system which was being worked in Germany. An aerial line, 628 miles in length, with 1,700 miles of wire and 27 offices, was opened on January 1, 1857, but, owing to the use of bad material, great difficulties were experienced in that damp and stormy climate in maintaining the lines and obtaining a sufficiently high insulation. In 1860 a direct Danish-English cable was laid, and as this increased the traffic the efficient working of the Danish landlines became more urgent and it was decided to abandon the old system and construct new and overhead lines with impregnated wooden poles and galvanised wire. The poles were cut in the great forests near Soroe, from which place more than 100,000 have been sent out, and were treated according to Boucherie's method. Some are still sound and standing after 20 or 30 years. A new porcelain insulator, for which a Danish labourer invented the screw, was adopted, and No. 5 galvanised iron wire was used for the international lines and No. 7 for the local circuits, the new lines being completed in 1863. Meanwhile lines connected with the State system were carried to the more retired parts of the country by private enterprise, all these lines being bought up by the State in 1871. The war with Germany and Austria in 1864 retarded the development of the Danish telegraphs for some years, and the loss of Schleswig and Holstein diminished the total length of its system by 400 miles. During the war the telegraph clerks followed the army and maintained communication between the different corps.

The establishment of the Great Northern Telegraph Company caused a great increase in the transit traffic. This company successfully connected the following countries by cable, with Fredericia in each case as the terminal office in Denmark :—In 1867 a cable was laid to Norway, in 1868 direct submarine connection was made with England, in 1869 a cable was submerged from Russia to Bornholm and the coast of Seeland, in 1873 an ocean line was laid between Fanoe and Calais and from Frederikshaven to Gothenburg in Sweden, thus embracing all the countries in the centre of which Denmark is situated. Fredericia may be regarded as perhaps the most important of all the telegraph stations in Northern Europe, because probably no other town is connected with so many foreign countries. The clerks there number between 80 and 90, and they work 35 Morse instruments, one Wheatstone duplex system to Copenhagen, and four Wheatstone circuits to the cables, where the ordinary receiver has been replaced by a fast-working recording apparatus, officially called "the Undulator," but familiarly known as "the Snake," which is able to receive from a Wheatstone transmitter at the rate of over 100 words a minute.

The number of telegrams (received and forwarded) dealt with at Fredericia has increased from 775,696 in 1879 to 1,462,930 in 1888. The messages handed in at Copenhagen have increased from 50,298 in 1865 to 192,946 in 1875, and to 344,297 in 1888. The development of the Danish telegraphs will be seen from the following figures :—

	1879.	1888.
No, of Telegraph Stations	124	165
No. of Telephone Stations	3—	40
No. of Staff	76	483
No. of Telegrams	969 123	1,525,268
Length of line (miles, English)	1,829	2,292
Length of wire (miles „)	4,842	6,205

The Leclanché cell is exclusively used in Denmark, and the open circuit system is employed, except on some less important lines, where several stations are placed in the closed circuit, which works well. The total number of telegrams exchanged between Denmark and some of the most important countries in 1888 is shown below :—

Germany	175,617	Russia	30,835
England	143,252	France	11,647
Sweden	91,468	Holland	9,033
Norway	36,166		

At first the charge for inland messages was at the rate of 2s. 2d. for 20 words, but it is now only the equivalent of 6½d. for 20 words, and half that amount for every additional 10 words or less. Owing to the comparatively short distances between the towns, the good roads, and the railways, the post is a formidable rival to the telegraph ; still more so, however, is the telephone. In every town and in many villages there is a central telephone bureau, enabling one to converse with friends in other towns within a circle of 30 to 40 miles, and these lines are being rapidly extended. Most of the telephone wires are of Bessemer steel wire No. 14, carried on the tops of the houses. In Fredericia silicium copper wire 1·25mm. is employed.

The director of telegraphs receives £270 per annum, the engineer £200, managers of stations £140 to £155, clerks in charge £112 to £122, male operators £55 to £100, and female telegraphists £45 to £65. From an English point of view these salaries may look small, but in Denmark they are considered fairly good. Except in the case of some of the head officers, who are entitled to a pension, 5 per cent. is deducted from salaries, and a similar amount contributed by the State, towards funds to pay an annuity to widows and to provide for old and infirm *employés*.

The State has erected 50 telephone stations, principally on the west coast of Jutland. By this means the fishermen are able to communicate with fishmongers at a distance, and to get much better prices for their catch ; and, all lifeboat stations being connected by wire, the telephone is also of great service in winter in calling for assistance when a ship is in danger or ashore.

On the whole it cannot be denied that Denmark has made good use of Oersted's discovery. When extensions of the telegraph to small towns have been demanded the State has not asked so much "Will it pay ?" as will the station be of practical use in assisting the people to earn a livelihood or in saving life.

MEETINGS OF SCIENTIFIC SOCIETIES, &c.

(To-night) FRIDAY, February 28th.

ELECTRO-HARMONIC SOCIETY.

8 p.m. Ladies' Night. Amateur Concert in the Banquet Room at the St. James's Hall Restaurant.

SATURDAY, March 1st.

ROYAL INSTITUTION.

3 p.m. Lecture : "Electricity and Magnetism." By the Right Hon. Lord RAYLEIGH, F.R.S.

MONDAY, March 3rd.

ROYAL INSTITUTION.

5 p.m. General Monthly Meeting.

SOCIETY OF ENGINEERS.

7:30 p.m. Ordinary Meeting. Paper to be read : "The Application of Water-Pressure to Machine Tools and Appliances." By RALPH H. TWEDDELL, M.Inst.C.E.

TUESDAY, March 4th.

ROYAL INSTITUTION.

3 p.m. Lecture : "The Post-Darwinian Period." By Prof. G. J. ROMANES, F.R.S.

INSTITUTION OF CIVIL ENGINEERS.

8 p.m. Ordinary Meeting. Monthly ballot for members. Papers to be read with a view to discussion : "The Hawkesbury Bridge, New South Wales." By C. O. BURGE, M.Inst.C.E. "The Construction of the Dufferin Bridge over the Ganges at Benares." By F. T. G. WALTON, M.Inst.C.E. "The New Blackfriars Bridge on the London, Chatham, and Dover Railway." By G. E. W. CRUTTWELL, M.Inst.C.E.

WEDNESDAY, March 5th.

The Electrician.

Published every Friday. Price Fourpence; Post Free, Fourpence Halfpenny
Editorial, Publishing and Printing Offices:

No. 1, SALISBURY COURT, FLEET STREET, LONDON, E.C.

Telephone No. 2714. *Telegrams:* "ELECTRICIAN NEWSPAPER, LONDON."

All Communications to be addressed to "THE ELECTRICIAN," *1, Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to* "THE ELECTRICIAN."

All letters intended for insertion in "THE ELECTRICIAN," *or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

"THE ELECTRICIAN" *is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.*

"THE ELECTRICIAN" *is on sale at the railway bookstalls throughout the United Kingdom on Friday morning, and can be obtained of all Booksellers and Newsvendors; or direct from the Publishing Offices as above*

SPECIAL NOTICE.

Owing to the increase in the number of pages of "THE ELECTRICIAN," in order to partly cover the increased postage, we have been compelled to revise the rates for Foreign Subscriptions, which are now as follows:—

	3 months.			6 months.			12 months.	
	s.	d.		s.	d.		s.	d.
For Foreign Parts and Colonies:—								
Within Postal Union	6	6	...	12	6	...	24	0
Aden, Borneo, Ceylon, China, India, Japan, Java Labuan Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7	6	...	14	6	...	28	0
The rates for the United Kingdom remain as follows:—	5	0	...	10	0	...	19	6

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to the office.

TRADE ADVERTISEMENTS *intended for the current issue must be handed in not later than First Post on Thursday morning.*

SMALL PREPAID ADVERTISEMENTS *(for Rates see page xv.) are accepted up to 4:30 p.m. on Thursday.*

TECHNICAL PRINTING.

"THE ELECTRICIAN" PRINTING AND PUBLISHING COMPANY (LIMITED) *beg to inform Electricians, Electric Light Engineers, &c., that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

"THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK.

Royal 8vo, 5s., postage extra.

Early in each year is issued "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1889 Edition consisted of more than 600 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with popularly-written Biographical Notices of the leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

The issue for 1890, which is still further enlarged and improved (making 850 pages), is NOW READY. Orders should be forwarded at once to the Publishing Offices, Salisbury-court, Fleet-street, London, E.C.

UNDERGROUND SYSTEMS OF DISTRIBUTING ELECTRICITY.

Granting the truth of the maxim that there is safety in numbers, the condition of the underground distribution problem may well be considered healthy. Indeed it would almost seem as though the central station engineer were more likely to be overwhelmed by a plethora of systems than deterred by the lack of a satisfactory one. It may safely be said that in no branch of the electric industry has greater progress been made within the last two or three years than in this. We can congratulate ourselves, not only on the improvements which have taken place, but also on the increased confidence which the satisfactory working of underground systems in the meantime has inspired. This is particularly the case with mains for high-tension currents. Three years ago it was still an open question whether the distribution of such currents underground was commercially practicable, but of this there can no longer be any reasonable doubt; and while it is true that further improvements may still be looked for, the fact that it can be carried out in more than one way has been fairly proved.

The series of articles on underground mains concluded in our last number, and which has brought this subject prominently before our readers, makes it manifest from how many different standpoints workers in this field have proceeded. For the moment perhaps the number of complete "systems" may be somewhat a matter of regret, as tending to retard progress in the immediate future, but from the engineering side, the accumulated experiences which the commercial operation of all these different methods of constructing underground mains will furnish must result in the collection of a great number of important data which will bear good fruit later on. At the same time, it seems probable that, even when high and low tensions are taken into account,

Digitized by Google

there may never be quite the same uniformity in the methods of distributing electricity that has come to be the case with water and gas, since the distribution of electric current through copper conductors is a problem of a more elastic nature, if we may so term it, than that presented in the distribution of water and gas, and therefore admits of a greater variety of treatment.

Turning now to the systems themselves, it is satisfactory to find that wherever pipes or conduits have been used the difficulties which it was thought would arise from water getting in, and from general dampness have proved less than was anticipated. When the possibility of using bare conductors underground was first mooted, the chance of water filling the conduits was one of the strongest objections brought forward against their employment; and therefore it is pleasing to find the supposed difficulty has proved quite a bugbear, and that while the leakage of water into the pipes or conduits is usually small, it is, moreover, easily disposed of when it does happen. No doubt differences will be found in this respect in different localities, according as the soil is porous and dry or clayey and moist, and as the drainage is good or bad; but with the experience now gained there should be no great difficulty in dealing even with unfavourable conditions. The increase in the use of bare conductors, on insulating supports, for low-tension currents is a matter deserving close consideration, and has much to recommend it. While the conductors themselves are in their cheapest form, the durability of all the materials employed is beyond question, and when, as is often the case, the size of the feeders is calculated so that the fall of potential at full load is as nearly as possible the same on each, this method of construction does away with any chance of ill effects from heating the shorter feeders, on which the fall of potential is greatest. As yet the question has hardly come to the fore, but in view of the extension of electric lighting, when space under the roadway and footpaths will become even more valuable than at present, it would be interesting to have an approximate estimate of the relative amount of room which a given section of bare copper strip on insulators would occupy as compared with a similar section in cables. There is another thing about these bare copper conductors which recommends them, namely, that local connections are so easily and cheaply made. This is a matter of considerable importance in estimating the relative cost of different methods of construction, for if a conductor is cheap but requires expensive junction-boxes, it may be more expensive for local services when connections are frequent than a more costly conductor, but to which junctions are easily and cheaply made. While, however, thus speaking well of bare conductors we do not wish to decry such solid work as that in which the cables are laid in bitumen. There are elements of safety and durability which recommend this method, for in the bitumen we attain additional insulation and a perfect preservative. It has the merit of adapting itself easily to circumstances, and gets rid of questions of drainage and dampness of the soil, while differences of level are of secondary importance. The fact that this method has been so largely used, and at the same time so little has been said about it, is much in its favour, for underground mains when once they are in their places must be classed in the category of those things of which the less that is heard of them the better. The relative desirability of all the systems in use depends now chiefly on their cost, durability, and convenience. Of their relative cost much will depend on circumstances, and as to the two latter items, at present they must remain largely a matter of opinion, which only the experience of further use and the lapse of time can finally decide satisfactorily.

For high-tension work we find almost, if not quite, as great a variety of methods as for low tensions, though so far the largest experience seems to have been with Siemens' concentric cables in Italy and india-rubber-covered cables in England. India-rubber has indeed done yeoman service in this respect, and although on account of its expense a thoroughly efficient substitute would be very welcome, yet we think that companies employing high-tension currents would be wise to pause for the present, and very carefully weigh the question before adopting other means of insulation. Although the practicability of conveying high tensions underground has been thoroughly proved, yet there are, unfortunately, several things which make the public at present timid and observant when such currents are employed. Now, the great elements of success in central station supply are reliability and freedom from interruptions, and to sacrifice these in any way is to lose public confidence, which, once destroyed, is not easily attained again. Experiments with high-tension mains should therefore be tried on a small scale and where failure will disturb the rest of the supply as little as possible. The use of anything found satisfactory can then be afterwards extended, with thorough confidence in its ultimate success.

Altogether the future of underground distribution appears full of hope. Of the chief difficulties which beset it the back has been broken, and it has come into commercial use on a large scale. With the additional stimulus which the concurrent working of rival systems furnishes, further improvements in detail in all the various systems in use must rapidly take place, and we may confidently expect that little time will elapse before this portion of central station work has reached as great perfection as the rest.

THE INSTITUTION OF ELECTRICAL ENGINEERS.

SOME POINTS IN DYNAMO AND MOTOR DESIGN.*

BY W. B. ESSON, MEMBER.

Though the recent progress in dynamo construction has been of a highly satisfactory character, there still remain several points affecting design which have received but inadequate attention, and to which reference is seldom made outside the drawing office. In the present Paper a few of these unsettled points will be brought before the Institution in the hope that a full discussion will enable us to make some progress towards a solution of the various questions raised.

1. Magnetising Force for a Simple Magnetic Circuit.

Foremost amongst the factors which have contributed to the progress of recent years has been a more perfect comprehension of the laws of magnetic induction, and now, knowing the magnetic properties of the iron with which we deal, it is a perfectly easy matter to determine the magnetising force required to produce in any simple magnetic circuit of given configuration a specified induction. The formula of Drs. J. and E. Hopkinson, which was published in the *Philosophical Transactions* in 1886, is now adopted by most designers who desire to economise their time. Reduced to ampere turns, this formula for the magnetising force is—

$$A_1 = L f\left(\frac{N}{a}\right) + L_1 \cdot 8 \frac{v_1 N}{a_1} + L_2 f\left(\frac{v_2 N}{a_2}\right) + L_3 f\left(\frac{v_2 N}{a_3}\right) + \ldots.$$

Here A_1 is the magnetising force; L, L_1, L_2, and L_3, are the mean lengths, in centimetres, of the separate parts which constitute the magnetic circuit—comprising in this case armature core, air gaps, magnet limbs and yoke—while a, a_1, a_2, and a_3, are the cross sections, in square centimetres, of these several constituents. Owing to the spreading of the induction, it is necessary to assume the air gaps as having an extension beyond the polar area equal to ·8 of the distance between the armature core and the polar surface. Of the induction produced in the magnet cores, only the portion N, which passes through the armature and is enclosed by the coils at the brushes, is serviceable, the lines of force which choose a path outside the armature constituting a stray field which cannot be utilised. In

* Read before the Institution on February 20, 1890.

Digitized by Google

the above expression v_2 is the ratio of the induction in the magnets to that in the armature, the total lines induced being therefore v_2 N. Since in cylinder armatures some of the lines stray through the internal opening, in these the induction in the air gaps will be greater than N. If we call v_1 the ratio of the lines in the gap to the lines in the armature, the lines in the former will be v_1 N. The functions $f\left(\frac{N}{a}\right), f\left(\frac{v_2 N}{a_2}\right)$, &c., are read directly off the curves Figs. 1 and 2, where ordinates give the induction per square centimetre, and abscissæ the corresponding ampere-turns required per centimetre length. These curves are reduced from the results of Dr. John Hopkinson.

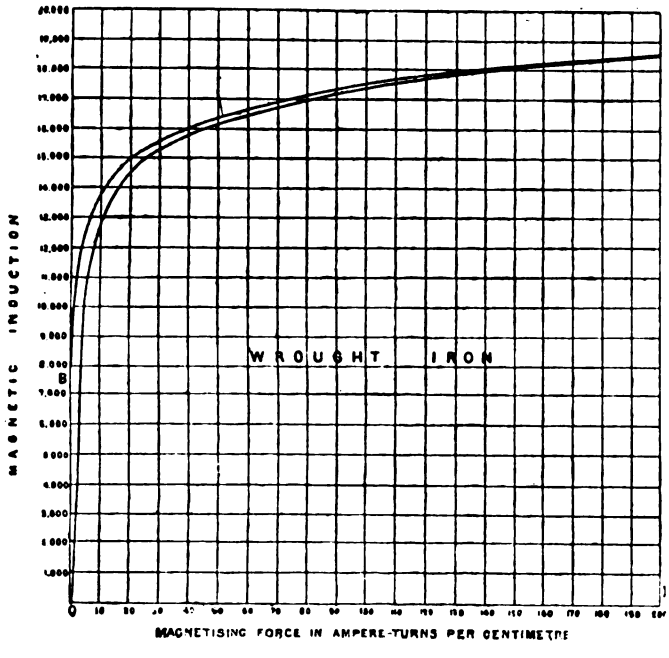

FIG. 1.

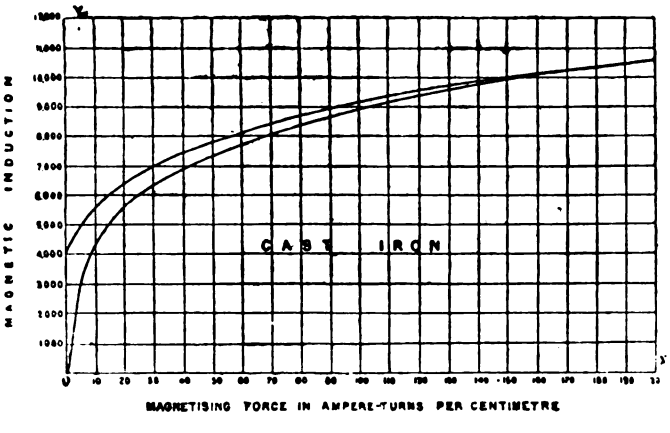

FIG. 2.

2. MAGNITUDE OF THE STRAY FIELD.

The expression in section 1 gives a general formula for any configuration of magnetic circuit, but in order to employ it, we require to know the values of v_1 and v_2, or, in other words, we must know the magnitude of the stray field. To be quite accurate, we should know the exact distribution of the field, for in any particular machine v_2 has evidently a different value at every part of the cross section. In the absence of actual measurement, however, its mean value can only be guessed at from a knowledge of machines of similar type.

The value of v_2 in different types of machines depends not only on the shape of the magnetic system, but on the position of adjacent masses of iron in bed-plates, bearing brackets, fly-wheel, &c. Calculations undertaken with a view to ascertaining its value from a knowledge of the shape of the machine, without reference to previous machines, are necessarily of a laborious character, and the labour in the end leads to no great accuracy. But I find that a very close approximation to the truth may be arrived at by taking the known value for some particular type of machine, and considering step by step the effect produced in the stray field by the changes in the dimensions and shape. It must be remembered that no two machines of the same type have exactly the same value of v_2 unless their dimensions correspond in every particular. Every alteration to the patterns, and every modification in the details, introduce a new value for this ratio. Our calculations, therefore, must be to a great extent guesswork. We cannot help it. If the guess is a good one, we congratulate ourselves on the soundness of our judgment, or on the accuracy with which we make our calculations. If it is a bad one, we write to the forge about the annealing of the iron.

The values of v_2 have been ascertained for the following machines, and it will be found, probably, that for all modern types they lie between these limits. With these values to guide us, we cannot go far astray in new designs.

TABLE I.—*Stray Field in Different Dynamos.*

Phœnix.....	Single Magnet, 2-pole (Fig. 8)	Cylinder	Yoke next bed-plate	1·32
Phœnix.....	Double Magnet, 2-pole (Fig. 3)	Cylinder	Horizontal	1·40
Manchester	Double Magnet, 2-pole	Cylinder	Bed and one pole cast together	1·49
Victoria	Double Magnet, 4-pole	Ring	Ordinary pattern	1·40
Ferranti	Double Magnet, Multipolar	Coreless Disc	Ordinary pattern (alternating)	2·00

The measurements of the Edison-Hopkinson and Manchester machines were made by Drs. J. and E. Hopkinson, of the Victoria by Mr. Mordey, of the Ferranti by Dr. W. E. Sumpner, and of the Phœnix by myself.

When the linear dimensions of a machine are increased in the same proportion, v_2 remains approximately unaltered. Suppose, for example, that all the dimensions of a magnetic system are increased n times. If the induction per square centimetre is the same, the total flux of lines is n^2. The cross-section of all the paths for stray lines are increased to n^2, and the distances between adjacent surfaces are increased n times. The lengths and cross sections of the stray paths are therefore increased in the same proportion as the useful paths, and the ratio between useful and useless lines is unchanged. If, the length of the magnetic circuit remaining the same, both dimensions of the cross section are increased n times, making the area n^2, the total flux through the machine is n^2; and since the cross-sections of the stray paths are n^2 times greater, the value of v_2 remains as before. If the length of every part of the magnetic circuit is increased in the same proportion, while the cross-section remains the same, v_2 is increased somewhat, owing to the increase in the cross-section of the stray path. If the dimension of either factor of the cross-section is increased, while the other is unchanged, and the length of the magnetic circuit remains the same, v_2 is reduced, its reduction depending upon the ratio of the two factors of the cross-section.

As the exact value of v_2 is a matter of some doubt until the machine is built, it may be instructive just to notice upon what the difference in the calculated flux through the armature, and the actual flux as modified by an error in the estimation of the stray field, depends. Assuming that we can measure accurately the path of the induction in the armature—often a matter of uncertainty—the magnetising force for the armature and the air gap can be determined independently of the magnitude of the stray field. The magnetising force to be allowed for the magnets depends, however, on the amount of stray field we assume. Imagine that in designing the machine we estimated a certain value for v_2, which turns out, when the machine is built, to be too low. Now the reduction in the flux through the armature due to this error will depend upon the magnetising force required for the magnets as compared with that required for the rest of the machine, and on the difference in the magnetising forces necessary for the induction in the magnets under the real and assumed values of v_2. If these two quantities are large, the error will be considerable, increasing as the magnets are more saturated, and as their resistance in proportion to the other components of the magnetic circuit increases. If the difference in the magnetising forces for the real and assumed values of v_2 is small, the converse holds good, the error being small in proportion. In the Edison-Hopkinson machine, for instance, the magnetising force required for the magnets is rather over one-eighth of the whole machine, and the value of v_2 is given in the table as 1·32. If in this machine an erroneous value of 1·25 had been estimated in designing, the diminution of the flux through

Digitized by Google

the armature, with the calculated ampere-turns so allowed for, would be only about 2 per cent., *i.e.*, the machine, to give the same output, would have to run at 765 revolutions instead of 750. If the magnets were saturated to a greater degree, or constituted a larger proportion of the magnetic resistance, the error would be correspondingly greater.

It must be noticed that the values in Table I. are given at the working saturation of the machine. As the bending in the magnetisation curve of the iron becomes more pronounced, v_2 increases. In actual machines we work above the bend, and with a reduced saturation v_2 would be less than given in the table. In practice, differences in the quality of the iron lead to much greater errors than are likely to arise from an error in the estimation of the stray field.

3. Symmetry of the Field.

It is of some importance to obtain a symmetrical field through the armature, as it is only when the field is symmetrical that the

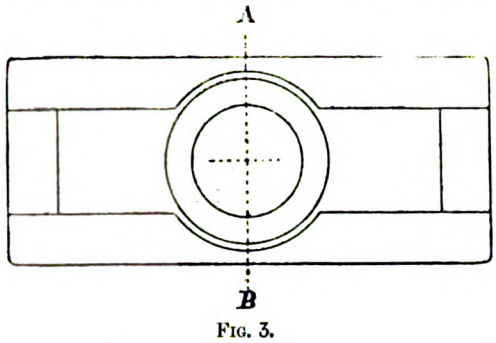

Fig. 3.

armature is electrically and magnetically balanced. Looking at Fig. 3, it will be observed that a line, A B, drawn diametrically across the armature divides it into two halves, which are perfectly similar as regards distribution of field ; and, generally, this is true of all machines in which there is a double magnetic circuit. There

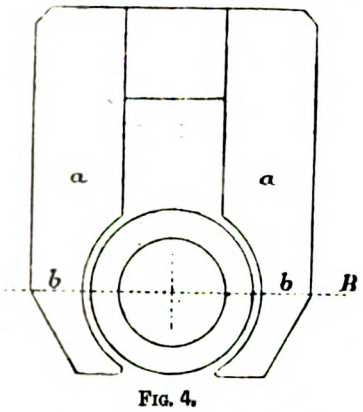

Fig. 4.

is here no tendency of the armature to move laterally in the field, providing its centre is concentric with the bore of the polar cavity. But with single magnet machines it is different. In Fig. 4, for example—which is about the worst form of magnet, on account of the section being reduced at *b* to half what it is at *a*—there is a

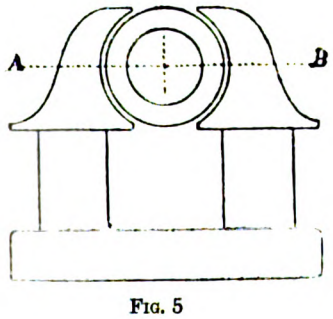

Fig. 5

strong upward magnetic pull, producing an abnormal pressure on the bearings, which may under some circumstances lead to serious trouble from heating. Most makers of single magnet machines have experienced some trouble from this cause, and have adopted, with more or less success, some means of curing the evil. A remarkable instance of the heating due to magnetic pressure on the bearings was recently brought to my notice by M. Heilmann, of the Société Alsacienne de Constructions Mécaniques, of Belfort. In the inverted machines first constructed by this Company, the magnet cores (Fig. 5) were of wrought iron, on the top of which were fitted cast-iron pole-pieces of comparatively small mass. From the look of the thing one would expect a very considerable downward pull, and in the case of some machines of 60,000 watt capacity the pressure on each bearing due to magnetic pull reached the high figure of 1,500 pounds. This, of course, led to serious heating, and in later machines the cylindrical wrought-iron cores have been continued to the top of the machine, as shown in Fig. 6, being fitted with cast-iron shells, which, together with the wrought-iron limbs, form, when bored out, the polar cavity. It will be noticed that the reduction in the section of the wrought iron due to boring out is very small, and I am informed that in this design the evil of heating has been completely abolished, a practically symmetrical field being produced. These machines are of the drum type.

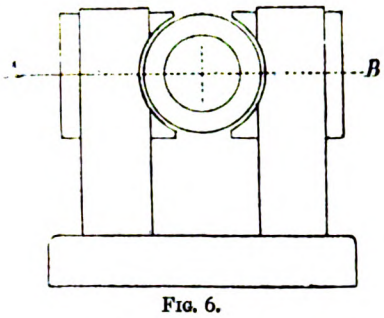

Fig. 6.

In well-designed machines of the single-magnet type there need be no trouble, however, from magnetic pull on the armature. The first essential is that the section at the thinnest part of the magnet be reduced as little as possible. The form in Fig. 6, for example, where this is carefully attended to, may be cited as an example of good design ; while that in Fig. 4 illustrates a magnetically bad design. Since the induction always takes the path of least resistance, the importance of keeping up the full section of the limbs at the poles, in order that the resistance due to saturation may not cause unequal distribution of the field, will be obvious.

The magnetic pull may be balanced by the very simple device of placing the armature eccentrically in the field, as I suggested two years ago,* its centre being somewhat farther from the yoke than the centre of the polar cavity. In some cases the magnets, after boring out, have been brought closer, so that the air gap increases

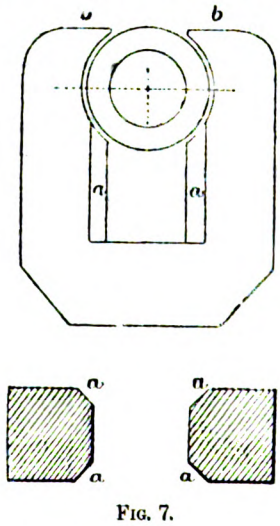

Fig. 7.

gradually to the polar tips ; but though the pull is reduced to some extent by these means, the device is not so efficacious as the one previously mentioned. I understand that in order to reduce heating this latter course had to be adopted in the machines built for the Bradford Corporation, the magnets in these being somewhat similar in shape to that shown in Fig. 4.

Electrically there is in drum armatures no want of balance due to an unsymmetrical field, as every convolution of the conductor encloses the whole of the lines of force passing through the armature core. The only result of a want of symmetry is that the position of the brushes on the commutator for a sparkless collection may become more marked, and the variation of current possible without readjustment of the brushes therefore less. But in cylinder-wound armatures not only is there a want of magnetic balance

* *The Electrician*, Vol. XX., page 114, 1887.

Digitized by Google

when the field is unsymmetrical, but from the fact that each convolution encloses only half the lines passing through the core there is a want of *electrical* balance, and it becomes, in consequence, doubly important to get a symmetrical induction, or the same number of lines through each half of the armature. Though the lines were unequally divided there might not be any appreciable difference in the E.M.F.s generated in each half with the brushes diametrically opposite; but from the fact that a want of electrical balance requires rather more lead to be given to the brush farther from the yoke, it is possible that the E.M.F.s in the two halves of the windings may be unequal, the result being a local current round the armature, and consequent waste of power.

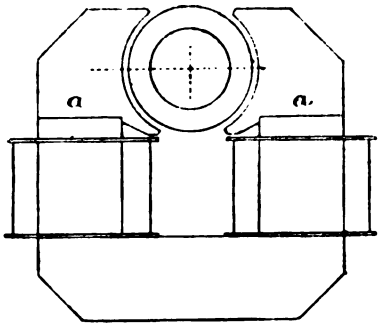

Fig. 8.

There are several methods of obtaining an approximately symmetrical field besides that already mentioned of placing the armature eccentrically in the cavity. What we have to do, if possible, is to make the path for the induction through the half of the cylinder

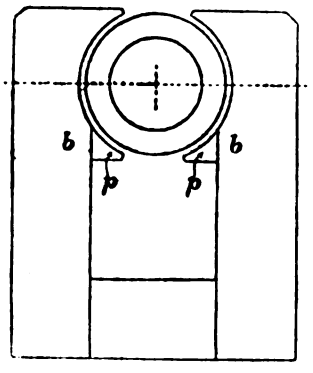

Fig. 9

core which is farther from the yoke of similar resistance to the path through the nearer half, so that a similar number of lines may flow through each. In the Phœnix dynamo we employ sometimes, with this object in view, the device shown in Fig. 7. Here the cast-iron

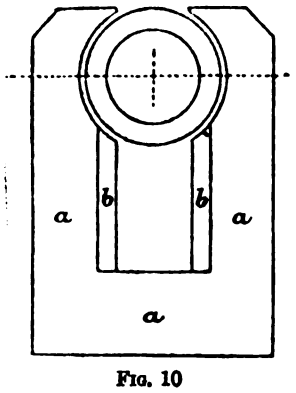

Fig. 10

magnet, instead of being rectangular in section, has the inside corners cut away, as shown in the section at *a*, the top corners at *b* being left on. In this way the magnetic resistance across the bottom path is increased, and the induction in the two halves of the armature made equal. Another plan is to shape the magnets as in Fig. 8, there being a faced joint at *a*. A plan adopted in several direct-driven ship sets we have just completed is shown in Fig. 9. The magnets are in this case of wrought iron, the limbs and top polar expansions being in one single forging, while the bottom polar expansions *p* are of cast iron. The magnetic resistance of the cast iron, combined with that of the joint at *b*, compensates for the diminished length of the induction path through the lower half of the armature. Another design by which the same end may be attained is shown in Fig. 10, where the magnet is partly of wrought iron, *a*, and of cast iron, *b*.

With a view to obtaining a more symmetrical field some single-magnet machines have been shaped as in Fig. 11. Here, to attain the object, the magnetic circuit requires to be lengthened, the magnetising force required being correspondingly greater. In Fig. 12 is sketched a single-magnet machine in which the field is quite symmetrical, although here the magnetic circuit has been made still longer.

It will be understood that it is possible to have an armature out of balance magnetically while electrically it is perfectly balanced, as, for example, a drum armature in the misshapen field, Fig. 4.

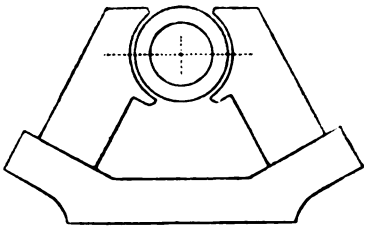

Fig. 11.

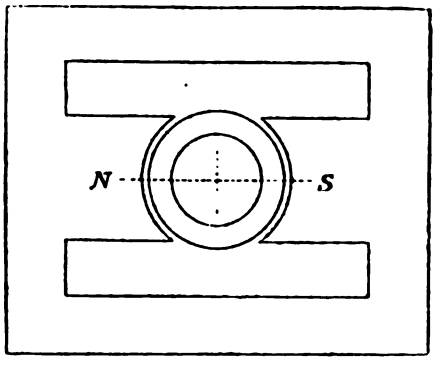

Fig. 12.

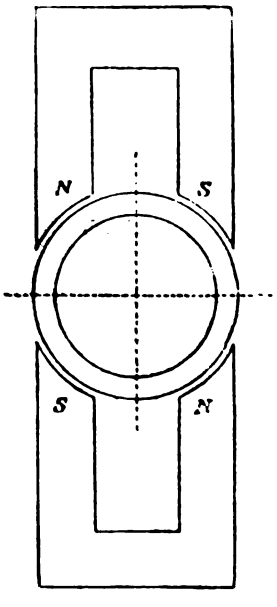

Fig. 13.

On the other hand, it is possible to have magnetic balance while electrically there is want of balance, as may be the case when a cylinder armature is placed in the four-pole field, Fig. 13.

When the armature core is carried round by spider arms, which fit into slots in the iron washers, it is important that the reduction of the core area due to these slots be as small as possible. Variation in the section causes magnetic kicks, or periodic fluctuations in the field during rotation.

THE WYNNE SYSTEM OF URBAN ELECTRIC TRACTION.

The following report, signed by Messrs. W. M. Mordey, John Raworth, and N. Scott Russell, has been sent us for publication :—

We have lately had an opportunity of examining a scheme which bids fair to solve the problem of electric traction on tramcars without the use of open conduits or accumulators. Mr. Frank Wynne, of 5, Westminster-chambers, is the inventor of the new system, in which power is transmitted from the engine to the car as directly as by rope traction, without the objectionable necessity of cutting a continuous slot in the roadway. Mr. Wynne has been engaged in endeavouring to solve the problem of urban electric tramways for upwards of four years. His efforts have been watched with keen interest by engineers and electricians in England, and the skill and foresight with which he has approached the subject have met with general recognition. While electricians and tramway companies in this country have been experimenting with accumulators and slotted conduits, tram lines with overhead conductors have been carrying all before them in America, and excellent commercial results have been obtained. The method of transmitting power to a tramcar by an overhead conductor, though well suited to new and rapidly developing districts, is absolutely inapplicable to English and most Continental cities, and no serious attempt has ever been made to introduce them in this country.

Fig. 1.

Mr. Wynne's new system secures all the advantages of an overhead conductor system without any of the constructive disadvantages of an open conduit. Among the chief advantages of the overhead system are that it enables ordinary permanent way to be utilised without reconstruction for heavier weights, and it allows of existing cars being used with some modifications. These advantages hold to the fullest extent in Mr. Wynne's system, the object of which is to enable the electric current to be transmitted direct from the generating station to the car motors through an insulated cable laid underground, after the manner of electric light cables, with absolute safeguards against the possibility of including any of the ordinary traffic of the street in the electric circuit. The current used is that known as the low-tension continuous current.

In the centre of the track is laid a crenellated contact plate or rail (*see* Fig. 1) in short sections. This contact plate or rail is not straight, but is formed to follow the junction line of the sets thus :— It is half-an-inch wide on the surface and about 4½ inches deep, it offers no obstruction to carriages crossing the track, and affords a good foothold for horses. Mr. Wynne has invented a remarkably simple device whereby the sections of the centre rail are successively put in connection with the main insulated conductor as the car passes over them, and are disconnected again as the car proceeds.

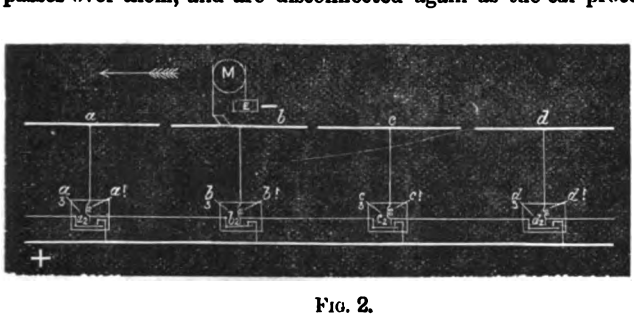

Fig. 2.

The only sections in connection with the main are those covered by the cars and its platforms : two sections are always in circuit, and a third section may be momentarily so connected as the contact brushes carried by the car pass over one of the separating spaces. The sections are necessarily short, and the inevitable leakage is therefore reduced to quite a negligible quantity.

The device for making contact with the sections of the central rail is shown in the following diagram (Fig. 2) : a, b, c, d are four sections of the sectional contact rail ; a^1, b^1, c^1, d^1 are electro-magnets traversed successively by the current passing from the main conductor + to the car motor M. a^2, b^2, c^2, d^2 are armatures and contact makers actuated severally by the electro-magnets, a^1, b^1, c^1, d^1, and are severally contained in the contact-boxes a^3, b^3, c^3, d^3. It will be noticed that as the car passes over section b, the current passing through the magnetic coil b^1 not only closes the contact in connection with its own magnet b^1, but also puts the magnet a^1 in circuit in parallel with b^1. This arrangement effectually obviates sparking, and provides that one section shall always be charged in advance of the contact brush. The contact pieces assume their original position by gravity, thus disconnecting the sections as the cars leave them. The contact boxes may be placed in any convenient position, as, for instance, in the footway or curbs, but their construction is such as to render them suitable for fixing in the tramway track. The boxes themselves are of cast iron or steel, with a grooved or "diamond" surface, and are constructed on the diving-bell principle, so that the enclosed air will absolutely debar water from rising into the interior.

It is obvious that it is an essential part of the scheme that the current should never be cut off entirely from the magnets, for under such circumstances they would break contact with the sectional rail, and the car could not proceed. Mr. Wynne has provided thoroughly practical devices both for maintaining the circuit and for re-making it in the event of accidental disturbance—as, for instance, by reason of the car leaving the rails.

Under ordinary circumstances a small percentage of the current is kept on when the motor has stopped, or when the car may be going down hill. In the event of contact being accidentally broken, the driver, by moving a lever, brings down a supplementary contact brush which closes the circuit of a single cell battery, and so re-establishes the current through the contact boxes.

There can be no doubt as to the great engineering skill displayed in Mr. Wynne's proposals, the details of which are eminently practical. The contact boxes are numerous, but there is no difficulty in adapting them to work under the conditions of a tramline, and the mere fact of the necessity of their manufacture in large quantities will reduce their cost and tend to simplify their details. This tendency is well illustrated by Lancashire cotton mills, in which 40,000 spindles are often found working all the year round, with scarcely any repairs. We are much impressed with Mr. Wynne's scheme, and consider that it is the only practical attempt that, up to the present, has been made to grapple with the real difficulties of urban electric traction. Batteries are ruinous at present prices, overhead conductors inadmissible in English towns, and open conduits are an aggravation of all the evils attendant on the use of straight rails in crowded streets. Mr. Wynne's invention has none of these drawbacks. We do not think that his crenellated contact rail would be in any way objectionable in well-laid roads such as are usually found in London and the principal provincial towns. On the question of capital cost and cost of power, we have carefully examined the accompanying estimates laid before us by Mr. Wynne, after comparing them with data derived from our own experience ; and we are of opinion that they are formed on a good commercial basis, a sufficient margin having been allowed for extras, which are inevitable in carrying out a new scheme. The estimate of capital expenditure for applying this system to an existing tramway, amounts, as shown, to £2,200 per mile of single track ; this leaves out the items of real estate and buildings, which will be much less for a line worked by electricity than for one worked by horses in which the area of ground and the buildings required for stables and granaries are very large. Against this capital expenditure of £2,200 per mile (including, as it does, boilers, engines, and dynamos for twice the maximum power required at any one time) must be set the capital cost of horses and of horse cars, amounting respectively to £1,500 and £500 per mile on the North Metropolitan Tramway, or altogether to a sum nearly equal to that for applying electricity. The large figure of 7½ electrical horse-power per car has been introduced with these estimates to cover a line with steep gradients and so make the estimate of safe general application. American experience shows that this is an ample allowance for the not very marked effect of gradients in increasing the aggregate power required.

Estimate of Capital Cost.

Tramline 4 miles in length, double track.
Generating station in centre, 2 miles from each end.
Average speed, 7 miles per hour.
Ten minutes' service.
Cars spaced 2,000 yards. apart.
Total cars in action at one time, 7.
Electric horse-power per car, 7½ = 5,600 watts.
Total electric horse-power, 52½ = 40,000 watts.
Voltage at generating station, 250.
Maximum loss 15 per cent. = under 40 volts.
Amperes per car in middle of line, 20.
Amperes per car at ends of line, 25.
Main conductor tapers in half-mile lengths from generating station to termini.

The lengths and sizes of conductors are as follows :—

2 half-mile lengths	.....	·195	square inch.
2 „ „	.....	·150	„ „
2 „ „	....	·103	„ „
2 „ „	....	·053	„ „

Digitized by Google

The most suitable cable for the purpose, having regard to the number of joints, will be Callender's bitumen insulated cable, which may be obtained at the following prices :—

1 mile ·195	£300
1 „ ·150	250
1 „ ·103	160
1 „ ·053	95
16 miles of junction wire, at £35	560
Roadwork at 2s. 6d. per yard	880
Casing at 2s. 6d. per yard	880
Joiners' work	500
Contact boxes (every 3 yards) at 15s.	3,600
Crenellated rail, 33 tons per mile, at £6 per ton	1,584
Supervision and sundries, at £100 per mile	800
Generating station for 120 E.H.P., being double the maximum power required at any one time for working the line, and including a complete duplicate plant of boilers, engines, and dynamos, at £30 per E.H.P.	3,600
11 cars (4 in reserve) complete with motor and fittings, at £400	4,400
Total	£17,609

Say £17,600 for the eight miles of single track, or £2,200 per mile.

Estimate of Cost of Power per car mile run.

It takes 1 horse-power hour to drive a tramcar one mile (this agrees with the results of extensive working in America). The cost of this, including coal, oil, waste, water, engineers, firemen, and dynamo men, with depreciation at 7½ per cent. per annum on half the generating plant, amounts to 1½d.

THE PHYSICAL SOCIETY.

At the meeting of this Society held on the 21st inst., the first communication was a short note by Mr. F. B. Hawes—

"On a Carbon Deposit in a Blake Telephone Transmitter."

The author exhibited some photographs of the diaphragm of a Blake Transmitter, on the centre of which a deposit of carbon had been formed after it had been in use for some months. The author attributed the deposit to particles being thrown off from the carbon button.

Mr. C. V. Boys stated that he had observed a deposit of a very similar character upon a sheet of glass, which had remained for some time very nearly in contact with one of the terminals of a dry pile.

Mr. A. P. Trotter then read a Paper on—

"The Geometrical Construction of Direct Reading Scales for Reflecting Instruments."

In the recent Paper by Prof. Ayrton, Mr. Mather, and Dr. Sumpner, on galvanometers, reference was made to the proportionality of deflection and current, and it was stated that the latest improvements in the D'Arsonval galvanometer had reduced the error to less than 0·15 per cent. within the ordinary limits of the instrument. The scale being flat, this means that the instrument is practically a tangent galvanometer. The improvements by which this admirable result has been obtained, are not applicable to most galvanometers, and there appears to be some difference of opinion as to its utility. The author of "Practical Electrical Measurement" says that "it is strange that so many physicists have taken so much trouble to design electrical measuring instruments to read proportionally," and adds "that when an instrument has its scale divided off into equal divisions, it must be regarded with suspicion." He has recently confirmed these views; but, since Prof. Ayrton has stated that "he does not agree that proportionality is a matter of indifference," and has observed that "it is extremely difficult to construct a 3ft. scale to follow all the vagaries of an instrument of the original D'Arsonval type," the author felt encouraged to call attention to the use of the bent scale, by which true proportionality can be obtained with the greatest ease. He was aware that this device was not new, but he had only heard of two instances in which it was regularly used.

For any reflecting instrument there are two limiting curves to which a uniformly divided scale may be bent to give the desired proportionality. The tangent to one of these curves, at the point where it cuts the horizontal axis or zero azimuth of the instrument, is perpendicular to that axis. The characteristic of the other curve is that it passes through the vertical axis of the mirror. When the angle of deflection is already proportional to the quantity to be measured, one form of the scale is obviously an arc of a circle coaxial with the mirror, but, owing to a property of the circle, the scale might be bent to an arc of half this radius—that is, of a circle passing through the axis of the mirror, and tangent to the usual scale line at the zero point (Fig. 1). Again, when the tangent of the angle of deflection is proportional to the quantity to be measured, the scale may be flat, or it may be bent to any of the curves shown in Fig. 2. The first of these curves is tangent both to the usual scale line, and to a line parallel to this, passing through the axis of the mirror. The others pass through the axis of the mirror, and are asymptotic to the scale line.

When the instrument follows some unknown law, the curves to which the scale may be bent may be found as follows, the methods being described as for a galvanometer, but, *mutatis mutandis*, they will be similar for any other instrument. Let five or six readings be taken at any convenient deflections, as, for example, those of the

Fig. 1.

ordinary reflecting galvanometer and of the ordinary D'Arsonval galvanometer, as given in the Paper already referred to. Set out the deflections on a sheet of paper, full size; the scale itself on which the readings were taken should be used if possible, and the lines drawn to converge towards a point at the scale distance. With a pair of dividers, take off on the scale a length proportional to the current or other quantity measured by the first deflection. Find two points, A and B (Fig. 3), the one on the zero line A O, and the other on the line of first deflection B P, whose distance apart

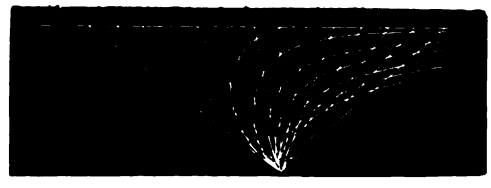

Fig. 2.

is equal to this length, and let these two points be equidistant from the point of convergence, so that the line joining them may be the base of an isosceles triangle. Then set the dividers to a length representing on the scale the increment of current required to produce the second deflection, and from the point B, the point already found on the line of the first deflection P B, mark off a point on the line of the second deflection. This process being repeated, a number of points may be found, and these, being joined by straight lines, a curve may be drawn between the inscribed and the circumscribing

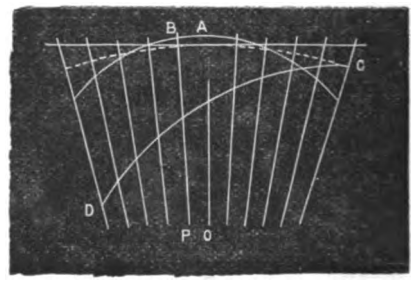

Fig. 3.

curve having the same length as the sum of the straight lines. The original scale being bent to this curve the readings will be proportional to the currents. The object of commencing with the isosceles is to produce a curve which shall be fairly continuous without any abrupt change at the point A where it cuts the zero line. The isosceles triangle is not always the best, but it is better than a right-angled triangle. This, of course, depends on the magnitude of the first increment. A slight change of curvature at the zero is of no importance.

When the sensitiveness increases with the deflection, the curvature is greater than an arc having the axis of the mirror at its centre. When it decreases the curvature is less, disappearing for a tangent instrument and becoming negative—that is, convex towards the mirror if the sensitiveness falls off very rapidly. The other limiting

Digitized by Google

curve which passes through the vertical axis of the mirror would seldom if ever be of any practical use; but between the two extremes lie a family of curves, some of which, either in whole or in part (one of these is shown at C D, Fig. 3), would be most suitable for ordinary use. The curve of least curvature would generally be the most convenient.

With an instrument which increases in sensitiveness with the deflections, to find the curve of least curvature it is best to commence with the extreme deflection, and setting the dividers to the last increment of current, find two points (A and B, Fig. 4) on the last two lines of deflection, forming the ends of an isosceles triangle. The other points may be found in the reverse direction. It is possible that in attempting to carry this out the increment of current at some point may not be sufficiently great to allow the line by whose length it is represented to bridge over between the two adjacent radial lines; in that case a fresh start must

Fig. 4.

be made a little nearer the centre, making a more acute angle at A (Figs. 5 and 6). The curve for the ordinary D'Arsonval (Fig. 5) and that for the ordinary reflecting galvanometer (Fig. 3), whose readings are given in the Paper already mentioned, lies partly within and partly beyond the usual scale distance, while the curve for a D'Arsonval with magnetic control (Fig. 6) lies wholly within the scale distance. A very small error at the commencement will throw the curve out or in by a very considerable amount, and at

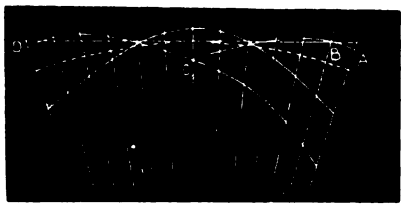

Fig. 5.

first sight this suggests that a serious cumulative error may be produced; but this is not the case, the error is confined to the particular portion in which it was made. Not only is there no danger of a cumulative error on this account, but, provided the zero and the extremity of the scale are each in the correct azimuth, any slight departure from the true curve will produce only an extremely small error in the readings if the curve is tolerably flat.

The use of dividers in taking lengths from a scale is open to several objections; in some engineers' drawing-offices their use is prohibited. The calculation of the increments of current involves subtraction, which is the most tiresome of the rules of arithmetic.

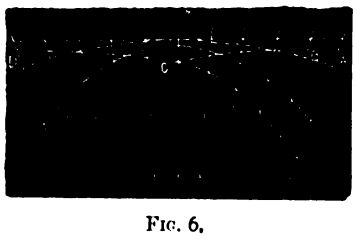

Fig. 6.

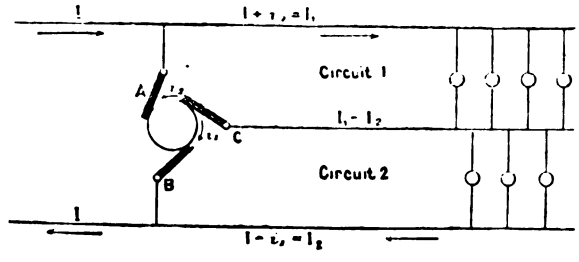
A more continuous method, by which both of these evils are avoided, is furnished by a strip of paper not more than half an inch wide; a piece of Morse ribbon answers perfectly. The current readings are marked on the edge, leaving a few inches over at each end. A fine needle is stuck into the paper at the starting point, and the end of the strip is fastened down with a drawing-pin. The strip, being narrow can easily be twisted through a quarter of a turn, and made to lie flat against the needle, making contact with it at the first current mark. The strip may then be swept round until the next current mark is perpendicular to the corresponding deflection line, and a needle is stuck in to mark the point. The other points may then be found with great rapidity and accuracy.

After crossing the zero line, the curvature generally increases rapidly, and the curve rapidly approaches the mirror. This would generally be open to the objection that the spot of light would get out of focus; but the use of a scale curved to such a shape would often be so convenient that it would be worth while in some cases to work with a parallel beam, or with cylindrical mirrors or lenses, to enable it to be used. For general purposes, where such an innovation as this could not be allowed, a fairly flat scale may be made from the two halves of the curve just described, making an obtuse angle at zero, or at any other point or points near the middle of the scale, as at A C D, Figs. 4, 5, and 6. Such a scale would generally be flat enough to allow the spot to remain in focus. The simplest way to deal with the curve, when found, would be to paste it on a piece of thin board, and cut along it with a band saw. The scale, mounted on card or metal, could then be nipped between the two pieces. There is evidently a connection between the polar curves to which the scale may be thus bent and the Cartesian curve, which shows the relation of the deflection to the current. This relation is not dealt with here, as there does not appear to be any simple geometrical connection between the two. These polar curves could probably be investigated most readily by Whewell's method of intrinsic equations.

THE ELECTRICAL DISTRIBUTION OF ENERGY BY THE THREE-WIRE SYSTEM.*

The advantages of the three-wire system are well known, and the saving of 68 per cent. in copper which was claimed for it has been verified by experience. This point being now admitted and experimentally demonstrated, it is only a question of ascertaining what are the most practical working conditions.

The most important problem in a three-wire system is to divide the current consumption as equally as possible between the two circuits. In many instances, when the three-wire system was first started in America, the inconvenience of having too many lamps alight in one circuit and too few in the other was obviated by taking the three wires into the consumers' premises, and the consumers, by means of special switches, changed their lamps from one circuit to the other as was necessary. As a rule, however, the very elementary precaution of dividing the consumers nearly equally between the two circuits is sufficient for all practical purposes. Let us now consider cases which may arise, distinguishing between a system of mains fed by two dynamos and by one dynamo.



The first case presents no difficulty whatever. The dynamos may be driven either separately or off the same countershafting, according as advantage is or is not taken of a variable cut-off to alter the speed of the dynamo. The only essential is a rheostat inserted in the exciting circuit of each machine. The cross-section of the neutral wire is one-half that of the two outer wires, so that it is possible to have a consumption twice as great on one circuit as on the other. It is evident that the inevitable variations of potential on the line must be remedied by the rheostat in the exciting circuit, but this is not difficult to accomplish. Care must be taken, however, to employ pilot lamps on the leads.

When only one dynamo is employed it is necessary to have recourse to certain special dispositions. The problem has been much studied and has received several solutions. Elihu Thomson employs one large machine, and in parallel with it two small machines, the armatures of which are mounted on the same spindle. The neutral wire is connected to the inner ends of these two armatures, the outer wires of the circuit being joined to the outer ends of the armature coils. If, therefore, one of the circuits is more heavily burdened than the other, the armature of the lighter circuit will be traversed by a current and will act as a motor, driving the machine of the heavily burdened circuit as a dynamo, the E.M.F. of which will compensate for the volts lost on the line. Accumulators may also be used as electric fly-wheels.

In the *Elektrotechnische Zeitschrift* Herr Hermann Müller describes another method. He proposes to employ a small two-pole machine with three brushes, A, B, C (*see* Figure), brushes A and B being

* From *l'Électricien*, February 8, 1890.

Digitized by Google

connected to the two outer wires, and brush C to the neutral wire. When the two circuits are balanced the machine is a motor running light. If the consumption increases on one of the circuits, I_1 becomes greater than I_2, the neutral wire is traversed by a current, $I_1 - I_2$, and a current, i_1, passes through the armature from C to B. The machine then revolves as a motor, and there is a production of mechanical energy, which is transformed into electrical energy in circuit 1. An E.M.F. is generated in A C, which is added to that already existing, and compensates for the extra volts lost on the line owing to the increased current. If we denote the current coming direct from the generator by I, the current passing from C to B by i_1, and that passing from C to A by i_2, we have

$$I_1 = I + i_2;$$
$$I_2 = I - i_1.$$

But the current i_2 produced by the rotation of the armature is sensibly equal to i_1, which causes that rotation. Hence i_1 being equal to i_2, we have

$$I_1 + I_2 = 2 \times I;$$
$$I = \frac{I_1 + I_2}{2}.$$

The tendency of this arrangement is, therefore, to make the total current at any instant the arithmetic mean of the currents in the two circuits. Half the armature always acts as a motor, one of the remaining quarters acting as a motor and the other as a dynamo. The idea is undoubtedly ingenious, but it would be useful to know whether it has been put into practice, and, if so, whether the facts have verified the theory.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *February* 15, 1890.

The United States Government and the Telegraphs.—The subject of the postal telegraph system has, as I anticipated, been brought once more before the public. Postmaster-General Wannamaker, in Washington this week, went before the House Committee on Post Offices and Post Roads, and made a presentation of a scheme to which he gave his full support. It had been understood that the topic would come up, and the Committee had invited to be present Dr. Norvin Green, of the Western Union, and Albert Chandler, President of the Postal Telegraph Company. Neither gentleman appeared, however, and since then Dr. Norvin Green has declined to discuss the matter until he has read a copy of the Bill, and received a full report of the proceedings of the Committee. The Postmaster-General submitted the draft of a Bill which met his views on the subject. The first section establishes the "Limited Post and Telegraph Service" as a bureau of the Post Office department, and directs that all post offices in places where the free delivery system now exists, or may be established, shall be "postal telegraph stations," together with those in any other place where, in the judgment of the Postmaster-General, the wants of the public "may be supplied under the operation of this Act." It is then provided that the Postmaster-General, with the concurrence of the Secretary of the Treasury and of the Attorney-General, may sign certificates for 10 years with any telegraph company for the furnishing of lines or the transmission of dispatches. Dispatches are to be sent in order of filing. They may be prepaid by ordinary stamps if the words "postal telegram" are clearly written upon the blank, and dropped into the letter-box or post office. Money orders are to be sent by wire as soon as arrangements can be made under the proposed law for not more than double the rates now charged for domestic money orders in addition to double the charge for postal telegraphs of 20 words. The amount is limited to $100. For 20 words the charge is to be not over 10 cents to a point within the same State as the office the dispatch is sent from, and not over 25 cents for any distance under 1,300 miles. For greater distances the charge is left to the Postmaster-General's discretion. The amount to be appropriated for establishing this branch of the service is left blank in the draft of the Bill as proposed. When Mr. Wannamaker had finished his argument, and read the provisions of the Bill, he was asked a number of pertinent questions by a member of the Committee. He did not deem it advisable at the present time to establish a rate that would be uniform for messages over the whole of the country; it would be done, however, at some future time, and he was very much impressed with the desirability and feasibility of such a plan. He suggested, with regard to the *employés* at these Postal Telegraph stations, that they could act as operators as well as clerks, and it would be easy for them to learn to telegraph, as the art was now taught in a great many places. These *employés* could be supplied through the agency of the Civil Service Commission. His reason for limiting the duration of the proposed lease to ten years was generally because it was difficult to get capitalists who might desire to aid in developing the system to invest their money for a shorter time. He thought it would be a good thing for the Committees of Congress to fix the rates for messages in the proposed system, so that later the accusation could not be brought against the Postmaster-General that the action in fixing the rates had been arbitrary.

Electrical Execution.—The committee appointed by General Austin Lathrop, superintendent of prisons in this State, to test the efficiency of electrical appliances and dynamos placed in the State prisons for the execution of condemned murderers, has made its report. The gentlemen in question are Drs. MacDonald, Rockwell, and Landy. The report is very voluminous. The questions to be solved were, in the main, whether the apparatus would kill, and what number of volts would be necessary? With the alternating current it was found that about 900 volts was the maximum for horses and other large animals, and about 400 for smaller animals, human beings striking an unhappy average somewhere between. At Auburn a horse and a calf were successfully experimented upon, and the efforts made by Dr. Fell, of Buffalo, by the aid of improved machinery, to resuscitate them, failed entirely, thus proving, the report says, that it was not a case of suspended animation. The main expressions of opinion were that each one of the apparatus proved death could be successfully inflicted and the execution accomplished within four seconds. There is, in the commissioners' opinion, no cause for imagining that there will be any failure of results; but at the same time the committee report that they do not find the apparatus in readiness, and they consider the plants to have been imperfectly set up.

Municipal Lighting.—The question of the trial of lighting plants by municipalities has just come up again out West, in the city of Milwaukee, where the Union Labour party are agitating the subject. It has been claimed out there that the city is paying far too high a price for its light, whether gas or electrical, and it is proposed that the city shall lessen taxation by running its own plant, and thereby getting lights at at least half the rate. I need hardly say that such an idea is highly Utopian, and I might also remark that while a great many of the advocates of the scheme are truly sincere and honest, it does not appear that an overwhelming majority of them contribute to the expense of maintaining the city government. Col. Hinsey, who is the chairman of the City and Country Democratic Committees, expresses himself very sensibly on the subject in an interview. "I do not think it can be done as cheaply as by a private corporation. The great misfortune is that the city pays too much for its labour as compared with private enterprises. There is not a man in the city, county, State, or national employ who does not receive more for his services than he would be likely to get from a corporation. They peg away and try to get one of these situations, and they are no sooner seated than they want a rise of salary. I see this at almost every Session of the City Council. As president of the body, I am chairman of the Committee on Salaries. The *employés* tackle the aldermen and they have a wrestling match with the Committee to comply with the wishes of their constituents. They are all paid too much, comparatively, for the work they perform. Why, I thoroughly believe our waterworks could be run 30 per cent. cheaper by a private corporation for this very reason." This is sound common sense, and involves one of the leading principles of the whole argument against civic monopoly.

Utilising the Niagara Falls.—Once more the proposition to utilise Niagara comes up, but this time it is in more definite and practical shape than it has ever been before. There is a perfected plan, backed by money already subscribed, to utilise

Digitized by Google

the power of Niagara—that is, not the Falls themselves, but of the water head of the river above the Falls. The plan to be carried out is one that I have already outlined in these columns some time ago. It is to be put in force by the Niagara River Hydraulic Tunnel Power and Sewer Company. The idea is to tap the river some distance above the Falls, run a main tunnel with which shall connect 24 cross tunnels, and 12 race-ways, the whole costing in the neighbourhood of about £500,000. The power thus obtained, even if sold at a ridiculously small figure, will pay a good return on the investment. A great deal of it would be used directly in driving factories and mills some distance above the Falls, and the rest would be utilised in lighting and in the long-distance transmission of electricity. In fact, electricity plays a large part in the scheme, and it is whispered around that Mr. Edison will occupy an important position as consulting electrician to the enterprise, which will also be backed at least by one of the strongest houses in Wall-street. The water that is drawn off will not in any material sense lessen the quantity going over the falls. The beauty of the scene will also be preserved from the fact that the factories and manufacturing establishments will be quite remote from the Horseshoe and the American Falls, and that the main tunnel will discharge its waters, like a third fall, some distance below the present town. The place is a good one for manufacturing and for the distribution of goods, and there are, in a word, no difficulties to contend with other than those that can be overcome by the simplest rules of scientific and correct engineering.

The East Reading Electric Railway.—The progress of the electric railways in this country is watched with the greatest interest on all sides, and all the new statistics that are obtainable are scanned with close scrutiny. The report of the East Reading Electric Railway and Motor Company, of East Reading, Pa., for the year 1889, has just been presented, and it brings out some interesting facts. This road was installed a little more than a year ago on the Sprague system, in a location not particularly advantageous; and I may note, by the way, the fact that, so far, it seems to have been one of the predetermined conditions that electric railroads shall be assigned work in situations that are disadvantageous. Be this as it may, the results at Reading have been remarkably gratifying. The number of cars now equipped is four, and the annual report of the treasurer, just issued, shows that dividends at the rate of 8 per cent. per annum on the working capital have been paid, and that a large balance is left in the treasury. The operating expenses during the time were about 2·6 cents per passenger carried. Another interesting fact in connection with this report is that during the year the number of passengers carried was more than double the entire population of the City of Reading. This fact alone shows a popular appreciation that cannot be disputed or denied.

Distribution of Power by Constant Circuit.—In a lecture just delivered by Mr. Elmer A. Sperry before the Chicago Electric Club, the speaker dealt with the problem of long-distance power transmission, and showed how the adoption of high potential for such distribution was an absolute necessity. In discussing the electrical methods to be adopted, Mr. Sperry was very decidedly in favour of distribution by constant-current as against the constant-potential method. He based his argument, first, on the fact that the difference of potential between any two points on the line of a constant-potential circuit was always the same, no matter what amount of power was being transmitted; hence the line was subjected to a maximum insulation strain at all times. On the other hand, with a constant-current distribution, the potential between any two points of the line would vary exactly in accordance with the amount of work being transmitted, and hence at low powers the strain on the insulation would be correspondingly reduced. Again, in support of his argument, Mr. Sperry cited the fact that a constant-current series dynamo for high potential is far cheaper to construct and maintain in good working order than a constant-potential shunt or a compound machine, and hence the advantage in employing the former. It is true an auxiliary dynamo might be employed with a special winding to excite the field magnets of the shunt machine, but this would involve additional complication. On the subject of regulating a constant-current motor, Mr. Sperry was of the opinion that there ought to be no difficulty in designing a mechanical governor which should be able to maintain the speed of constant-current motors within one or two per cent. for all loads—that is, equal to the performance of constant-potential machines at the present day.

PARIS NOTES.

(FROM OUR OWN CORRESPONDENT.)

February 25, 1890.

In my last letter I gave some particulars with regard to the system of distribution affected by M. Victor Popp, and I cannot do better this week than describe the Solignac system which it is proposed to work side by side with that of M. Popp. The ideas underlying M. Solignac's patents may be briefly stated as follows. It is not possible in practice to run alternators in parallel; on the contrary, it is easier to run high potential continuous-current machines in this way. On the other hand, continuous-current transformers have not up to the present been much employed, while alternate-current transformers have. Hence the system to be used is one in which high-tension continuous currents are rendered alternating, thus making it possible to use alternate-current transformers. The theory of M. Solignac seems to me somewhat defective, inasmuch as we have had as yet no example of high-tension continuous-current dynamos working in parallel, and because the conversion of the continuous current into an alternating one will certainly be accompanied by considerable loss. The apparatus with which it is proposed to effect this transformation is simply a rotating commutator introducing varying resistances into the primary circuit of an ordinary transformer placed across the mains, the coils of which are therefore traversed by a pulsating current. To prevent the commutator from being quickly destroyed, an air blast similar to that used by the Thomson-Houston Company is brought into play. The Solignac system was to be seen at work at the Exhibition supplying Jablochkoff candles. The purchase by the Popp Company of the Gaulard-Gibbs patents for France has, doubtless, something to do with their adoption of this wonderful alternate current system, which is worth noticing owing to the fact that there is some likelihood of its being actually worked in the district allotted to the Popp Company. Meanwhile M. Popp has received financial support from Berlin to the amount of over a million sterling, and proposes to erect a 20,000 horse-power generating station.

Last week there came on for hearing the action brought against the State by the Société Générale des Téléphones for the purpose of vindicating the validity of the agreement of July, 1886, between the Société and the Government. After hearing the arguments on either side the Court announced that judgment would be delivered in a week's time.

BRUSSELS NOTES.

(FROM OUR OWN CORRESPONDENT.)

BRUSSELS, *February* 21, 1890.

Since my last letter the only event of note has been two concluding debates at the Société Belge des Ingénieurs on the question of the electric lighting of the city. At the first of these debates M. Lucien Anspach combatted at one and the same time the hydro-electric scheme of M. Van Rysselberghe and the low-tension proposals of M. Bède, advocating continuous-current distribution at 2,000 volts pressure. Perhaps the most important outcome of the discussion was the decision to appoint a Technical Commission to examine M. Van Rysselberghe's turbine. At the second and final meeting M. Bède explained the Popp compressed air system at considerable length, and this series of conferences came to an end with an expression of confidence in the competence and patriotism of the Conseil Communal.

CORRESPONDENCE.

LIFE AND EFFICIENCY OF GLOW LAMPS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: There is such an interdependence between the life and efficiency of a glow lamp, that it is high time that one of these words should never be spoken of without the other; and for this purpose I think it would be most convenient if a standard efficiency (say 3½ watts per candle-power) were adopted for general use or as a reference, and that all lamps should be compared for life or durability at this standard efficiency.

The separate use of the above terms (life and efficiency) is a very attractive method of making misleading and utterly useless statements, which one daily meets with in technical and other papers. What value, for instance, have the following recent extracts beyond their misleading value?

In one of your contemporaries I read a note headed "Life of Incandescent Lamps." A certain 100 volt 16 candle-power Edison-Swan lamp is stated by Sir D. Solomons to have run for over 3,400 hours; but such a statement must be known to be useless without stating how many watts were required to produce the actual, or, at the very least, the nominal candle-power. Again, in *The Electrician* of the 14th inst. there appears an advertisement *re* Coad's battery. A report is given (in copy) stating "the cost per twelve hours of production of light," &c. Even supposing the word light to mean a light of one candle-power, then the omitting to say what number of watts this one candle-power requires leaves us to guess how much it would cost us for lamp renewals. Again, in the same number of *The Electrician* appears a note entitled "Mr. Edison and his Work," reprinted from *Harper's Magazine*. We are told that Mr. Edison has constructed "3,000 reasonable theories in connection with the electric light," &c., and "that Mr. Edison has now reached a point where he could maintain fully fifteen lamps to the horse-power;" but we are not told which of 3,000 equally reasonable theories we are to adopt respecting the life or duration of these same fifteen lamps.

I give below a test taken from an old note book of mine of 1883, which will show what can be asserted without a simultaneous use of the words life and efficiency:—

Candle-Power.	Watts per C.P.	Candles per E.H.P.	Notes.
10	3·08	242	Normal
15	2·63	...	...
20	1·97	...	...
25	1·66	...	...
30	1·48	...	...
35	1·36	...	...
40	1·25	...	...
50	1·05	710	...
60	0·92	...	...
70	0·83	...	...
80	0·75	...	...
100	0·63	...	...
200	0·41	...	...
300	0·28	...	...
400	0·21	3,552	Was not broken after running for 2 hours at same E.M.F.*

* Quite a sufficient time to show off the merits (?) of any battery.

A 50 volt 10 candle-power (normal) filament was mounted on extra thick platinum with extra heavy mounts, and gave the results set out.—Yours, &c.,

C. J. ROBERTSON, A.I.E.E.

Middelburg, Holland, February 19, 1890.

TELEPHONES FOR DOMESTIC USE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Without wishing to detract from Mr. A. A. Campbell Swinton any credit for originality in his arrangement of automatic switch, as defined in your issue of this date, I would ask permission to state that the method he uses, and patented in 1887, was anticipated in 1883 (No. 2,592) by Colonel G. E. Gouraud, who was then connected with this Company.

Our invention, which you kindly described in your issue of the 14th instant, is absolutely novel, inasmuch as in both the patent of Gouraud, 1883, and in that of Swinton, 1887, "the call" can *only* be made "when the telephone is off the hook." This is not so with ours, and moreover, sundry other conveniences occur in our invention that are absent in the others. For these details I would, with all respect, refer your readers to the usual Blue Book (Patent No. 5,867, 1889).—Yours, &c.,

W. J. M. MENZIES.

No. 109, Farringdon-road, London, E.C.,
February 21, 1890.

CARRARA ELECTRIC LIGHT.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Surely there must be some mistake about the paragraph under this head in yesterday's *Electrician*.

It is said that 350 16 candle-power lamps and 25 arcs are to be supplied by using a waterfall of 27 gallons a *minute* falling 260ft. I suppose this number of lights would at a moderate computation require 75 horse-power. Now, the gross horse-power of the waterfall is only $\frac{27 \times 10 \times 260}{33{,}000} = 2{\cdot}13$ horse-power. Allowing the turbines an efficiency of 75 per cent., this gives a net horse-power of about 1·6. Perhaps for *minute* we should read *second*. This would give $1{\cdot}6 \times 60 = 96$ horse-power, which may be what is really required, unless the engineers adopt a wonderful American water machine, which the agent assured me delivered 10 horse-power for every one horse-power put into it. I suggested that this should pump water to work a second engine, which would convert the 10 horse-power into 100 horse-power, and so on, until I showed him that an engine of 1 mouse-power could, by this "series system" drive the "City of Rome" through the Atlantic As I would not believe the agent's assurances, he told a friend of mine that I was "the cussedest conservative he ever 'lighted on," and so I remain—Yours, &c.,

72, South-mall, Cork, February 22, 1890. DENNY LANE.

[The alteration suggested by our correspondent is probably the correct one, and we regret the figures were inserted without being tested for accuracy.—ED. *E.*]

THE ETHER THEORY OF 1839.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I sent Dr. Lodge a copy of the first part of my book entitled "The Ether Theory of 1839 is the True Theory of the Leyden Jar." Having received from him a letter, which I saw might do good if published, in that it would give editors and others freedom to write without bias on the subject, I requested Dr. Lodge's permission to publish it, and, as he has consented, I send you a copy.—Yours, &c., JAMES JOHNSTONE.

8, Merchiston Park, Edinburgh, February 20, 1890.

[COPY.]

"21, Waverley-road, Liverpool,
"February 15, 1890.

"To James Johnstone, Esq.,

"Dear Sir: I am indebted to you for a pamphlet in which you subject my little book, "Modern Views," to a criticism which cannot but be wholesome.

"It depends on what is meant by 'electricity passing through glass.' In a sense it certainly does, but not by conduction. I expect you have got hold of a true idea in connection with the matter.—Yours truly,

(Signed) "OLIVER J. LODGE."

LEGAL INTELLIGENCE.

Chatenay v. Brazilian Submarine Telegraph Company.

This case came before Justices Denman and Vaughan Williams, in the Divisional Court of the Queen's Bench Division of the High Court of Justice on Friday last, by way of an application by the plaintiff to vary an order made by Baron Pollock in chambers.

Mr. H. D. GREENE, who, with Mr. Alexander Young, appeared for the plaintiff, said the issue to be tried had been directed by the court under the following circumstances:—Mr. Chatenay, who resided in Brazil, was on the

Digitized by Google

register of shareholders of the defendant company, and, finding that his name had been removed therefrom, he applied under Section 25 of the Companies Act, 1862, to have it restored, because he contended that his name had been removed without lawful or just cause. Thereupon the Court ordered that an issue should be tried, whether the plaintiff's name had or had not been improperly removed, and this issue was now waiting trial before a jury. The defendant company, in answer to the plaintiff's complaint as to having taken his name off the list of shareholders, said that he (the plaintiff) having given a power of attorney to a gentleman in London, they (the company), acting on that power, had transferred the shares out of the plaintiff's name. The defendants contended that Brazilian law, and not English law, would govern the construction of the power of attorney, and, that being so, it gave a general power to the holder to act in the way he had done. Mr. Chatenay, on the other hand, said the power of attorney must be read according to the law of England, and, so reading it, it was clearly a limited power, and did not authorise what had been done. In August last the defendants applied to the Master for a commission to go out to Brazil to examine witnesses as to how the authority would be determined by the Brazilian Courts. The Master refused this application, holding that it was entirely a matter for the English Courts. Thereupon the defendants appealed to Baron Pollock, who referred the matter for the decision of the judge at the trial of the issue.

Mr. FINLAY, Q.C. (with him Mr. W. GRAHAM), represented the defendants. He said if all that the plaintiff wanted was to have the question of whether the Brazilian law or the English law governed the matter tried as a preliminary question before a judge without a jury, he should not object.

Mr. GREENE acquiescing in this, their Lordships ordered the question to be tried before a judge.

In re JAMES FYFE.—The statement of affairs under the failure of James Fyfe, described as of St. Stephen's Chambers, Telegraph-street, City, has been issued. The debtor states that he is an electrician, and that for two years prior to May, 1884, he acted as managing director to an electric light company in which he had a large interest. He attributes his insolvency to his inability to realise certain property without resorting to litigation, which he considers would be necessary to establish his claims. The receiving order was made in December last, and the statement of affairs now furnished shows gross liabilities £18,707, of which £17,408 are fully secured, and assets of uncertain value. The securities held by creditors, treated as fully secured, are stated to consist of shares in electric light companies (estimated at £4,336) and patents for electric lighting (£14,000). The bankrupt considers that a surplus of £927 might be realised on some of the shares.

TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning.*]

"THE ELECTRICIAN"

ELECTRICAL TRADES' DIRECTORY & HANDBOOK for 1890

The new edition of our well-known Directory and Handbook is now ready. The book consists of 850 pages, and has entailed this year an exceptionally heavy amount of work. The HANDBOOK DIVISION contains a mass of most useful information. The DIRECTORY DIVISION consists of more than 400 pages, and contains a very carefully compiled Alphabetical and Classified List of Firms and Persons engaged in the Electrical and Allied Trades in all parts of the world. This Division has been corrected up to date, and the book is thoroughly reliable, even the very numerous changes which take place in the month of January being incorporated. The book is not a mere list of Members of Scientific Societies repeated again and again. The Colonial and Foreign Division will be found extensive and reliable. The book has been very favourably reviewed by the Press. *Orders should be forwarded at once.*

TENDERS INVITED.—The Director of Army Contracts invites tenders for the purchase of scrap iron, steel, &c., for one year, from April 1st next. Tenders must reach the War Office, Pall Mall, London, S.W., by 12 o'clock on Friday, March 14th.

MESSRS. BLENHEIM AND CO.—This company have recently received an order to fix their improved system of street fire alarm telegraphs for the district of the Local Board of South Hornsey, and also an order to re-wire the telephone exchange and electric bell system at the St. Saviour's Union, Dulwich.

BLAMIRE'S PATENT INDICATING APPARATUS.—We have received a circular describing this invention, which is "to enable masters, managers, or foremen to ascertain at any time or place whether any machinery, engines, or tools are standing or are in motion, and doing their proper work." This operation is performed by a special arrangement of electrical communication. It is claimed by the inventors that for the application of this apparatus any existing telegraph, telephone, or other established electrical circuits can conveniently be adapted without interfering with other instruments.

SALES BY AUCTION.—Our readers are reminded that Mr. Alfred V. Robinson will offer for sale at the Mart, Tokenhouse-yard, E.C., on Tuesday next, at two o'clock, the valuable leasehold electrical manufacturing premises at Pownall-road, Haggerston, London, N.E. Further particulars will be found on page III. of our advertisements.

——— Some valuable freehold property, suitable for manufacturing electricians, electrical engineers, &c., situate at Dalston, N.E., will be offered for sale on Tuesday, March 11th, by Messrs. Thurgood and Martin, of Chancery-lane, E.C.

PERSONAL.—Mr. R. Lewis Cousens sails for South Africa in a few days to represent Woodhouse and Rawson United (Limited), in South Africa. The firm intend to keep at their new offices in Johannesburg a large stock of electrical machinery and accessories.

BUSINESS TRANSFER.—We are informed that Messrs. Pontifex and Wood (Limited), the well-known ironfounders, engineers, and coppersmiths, of the Farringdon Works, Shoe-lane, E.C., have transferred their Millwall metallurgical works and white lead business to the Millwall Lead Company (Limited), of 17, Philpot-lane, E.C., and Millwall. In future the only address of Messrs. Pontifex and Wood (Limited) will be the Farringdon Works, Shoe-lane, E.C., where the engineering business will be carried on as usual.

THE THOMSON-HOUSTON ELECTRIC MOTOR.—We have received from the Thomson-Houston Motor Company of America, a handsomely got-up pamphlet, describing the mechanical design, regulation, rheostat, tests, and classification of the Thomson-Houston motor. Illustrated descriptions are given of the application of the motor to mills, tramways, printing machines, electric hoists, mining, mining locomotives, drawbridges, shoemaking machines, and general tramway work. The brochure contains a number of full-page illustrations, showing the motor at work in printing offices, harness and saddlery warehouse, shoemaking shops, &c., and illustrated details of the construction of the machine are also given.

PATENT RECORD.

APPLICATIONS FOR PATENTS.

January 30, 1890.

1,629. A. J. BOULT. London. Improvements in or relating to electric accumulators (G. G. A. Giovanni, Italy).

1,638. H. M. HARCOURT. London. Electric automatic railway alarm and signalling device and apparatus.

1,644. A. L. LINEFF. London. Improvements relating to electric traction.

1,646. P. C. BREWSTER. London. Improvements in safety devices for electric lines.

1,658. C. P. ELIESON. London. Improvements in and connected with electricity meters.

February 1, 1890.

1,768. J. SAX and E. DONOHOE. London. Improvements in apparatus for electrically indicating or recording the number of times that a closet lavatory or the like is used.

February 3, 1890.

1,734. T. A. GARRETT. London. Improvements in and connected with the production of ozone by means of electricity.

1,822. J. LEE. London. Improvements in electrically-actuated whistles, trumpets, and horns, and in speaking tubes for domestic and business use, for hotels, for train intercommunication, and other purposes.

SPECIFICATIONS PUBLISHED.

1889.

3,365. KAMM. Electrical conductors. (Price 8d.)

THE NORTHERN ELECTRIC WIRE AND CABLE MANUFACTURING COMPANY (LIMITED).—The first annual meeting of this Company was held at the Company's offices, Square-road, Halifax, on the 18th inst. The Directors report a rapidly increasing business, and congratulate the shareholders on the good prospects before the Company. After stating that the profits are over 10 per cent. for the year, the Directors recommend a dividend of 7½ per cent., placing the balance to a reserve fund, which was agreed to, and after the usual vote of thanks the meeting closed.

COMPANIES' MEETINGS & REPORTS.

The Notting Hill Electric Lighting Company (Limited).

The ordinary and extraordinary general meetings of this Company were held on Tuesday last, at the offices of the Company, 9, Austinfriars, London, E.C., Mr. William Crookes, F.R.S., the Chairman, presiding.

The SECRETARY (Mr. W. H. Fox) read the notice convening the meeting and the minutes of the extraordinary general meeting of November 27, 1889, which were confirmed and signed by the Chairman.

The CHAIRMAN: Gentlemen, there is no special business before the meeting, but the Directors thought that as soon as possible after the general allotment, the shareholders should be asked to come together to receive information as to the state of affairs, and have the opportunity of asking any questions they might like to put to us. I may as well give a short history of the Company. The date of the registration was just about two years ago—in February, 1888; and the statutory general meeting was held on June 6, 1888. The second general meeting was held on the 3rd October, 1889. The Act of Parliament obtained the Royal assent on August 26, 1889, and this Act gives the Company a practical monopoly over the whole of the area which is assigned to us. You had with the prospectus a small lithograph, showing the area given, and behind you is a large map, 5ft. to the mile, on which the area is outlined, showing all the streets existing up to the present date. The Directors of the Company, who for nearly two years were the only shareholders, gave a very great deal of time and trouble to the matter, for we had about fifty board meetings, and besides that there was a very great number of informal meetings at the houses of the different Directors, and meetings at the vestry late at night and early in the morning: meetings before the Board of Trade; meetings at Major Marindin's Committee, where some of us had to be in attendance the whole time, and meetings in obtaining the Provisional Order before Parliament. Of course, up to the time of going to allotment the expenses of all this, which amounted to about £1,500, were paid out of funds which the Directors themselves supplied. The results of the recent application to the public are these:—We have got about £70,000 subscribed, and that the Board consider is quite sufficient to carry out the whole of the lighting of this large district in the terms of the Act. This has enabled us to apply for a special settlement and quotation on the Stock Exchange, and it is hoped that that quotation will be granted. The Secretary of the Stock Exchange has suggested that we should alter one of the Articles, and the extraordinary general meeting to-day is called for the purpose of altering that Article. Since we were able to see that a certain amount of money was likely to be at our disposal, we have been very busy in pushing forward the subject of getting estimates, which was necessarily going on rather slackly before. All the preliminaries were well advanced; and now we have estimates from different firms for supplying the machinery. I believe, in the prospectus, it was stated that we had only a lease of the land for the central station; but we have now purchased the freehold at an additional expense of £1,350, and on the map the red dot shows where the central station will be. It is very centrally situated for the greater part—over one-half of the district—and occupies, I think, about as good a position as we could possibly get at the price, and is almost the only position available. The amount of capital called up is £14,800. There is a sum of money on deposit at present, which is earning more than sufficient to pay the current office expenses, but I am afraid we shall soon have to take it out of deposit, because the expenses now are of course running on, and we shall have to pay for the machinery. The contracts entered into amount to about £24,000, but we shall not have to pay the whole of them at once—that will run over the rest of this year. We have plenty of cash in hand, therefore, for the present, and if a call is necessary later on it is expected that there will not be required more than £2. 10s. up to the end of the year. The land will cost about £6,000: the machinery will be about £7,000; the building about £4,000; and putting down the mains in certain streets, which we consider it advisable to take first, will cost about £7,000, making a total of £24,000, which will have to be paid during the present year. In the prospectus it was stated that the preliminary cost would not exceed £4,000, and a statement which has just been made to us by the secretary shows that the original cost is slightly under that amount. With regard to mains, of course a great part of our area consists of very good highly-rented residential houses, from which we may reasonably expect to get good customers. A smaller portion of them, especially near the outlying districts, consists of rather poorer houses, and it is not likely we shall have a great many customers from among them, so it has been decided to divide the area into about three parts. The first is represented on the tracing before you, which is on the same scale as the ordnance map. The tracing shows the mains we are going to lay down first, at an expenditure of about £7,000. This includes nearly the whole northern part of the parish, and comprises the greater part of the compulsory area in that portion of the district. As soon as we have got fairly on the way with that, we shall attack the rest of the compulsory area mentioned in the Order, including all the streets that we are obliged to light within two years; and we are in hopes, if things go on well, we shall have the second lot of mains in an advanced state by the end of the year. I do not like to prophesy until a thing has happened, but, judging from the results obtained in a neighbouring electric light district, from which we have derived a great deal of experience—we have got the benefit of their experience and the results of the unavoidable little mistakes and errors which are always made in starting a new thing—to judge from the results that have taken place in that district, with a class of houses very similar to a good many of the houses that we should have, it is found that between 30 and 35 houses will pay expenses. I think that we can see our way certainly to between 50 to 100 houses to start with. We have definite orders for a great many, and I know personal friends of my own in the district, and friends of the Directors, who, as soon as the mains come near the houses, will have their houses wired; so that I think there is no doubt whatever that very soon we shall get over the magic number thirty, which will clear working expenses, when the rest will be bringing in profit. Then it is shown that the first 200 houses brought in £3,000 a year profit; and the first 400 produced £7,000 profit. We have over 4,000 houses in our district, so I think before the end of the year we shall be getting a certain amount of revenue, and I hope securing a very nice profit. The engineer for an adjoining company, the Kensington and Knightsbridge Company, is also our own consulting engineer—I mean Mr. Crompton. He has had, I think without exception, the largest experience of anyone in the world in laying down mains and lighting large districts from a central station. He has tried many plans for laying down mains, and has at last come to the very definite conclusion that a certain plan which is being adopted in the Kensington and Knightsbridge district, and a great many other places in England, is, without exception, the best as well as the cheapest and safest method of laying mains. He has given us full plans and details of the method of doing it, and the subject is before the Directors now as to how far we shall adopt the plans he has recommended. I do not think there is anything else to say now, but, of course, there may be several questions which shareholders would like to ask, therefore I will conclude by saying that we shall be very happy indeed to give every information possible. We want to give the shareholders every possible information that they can require, for I do not agree with keeping anything dark in a matter like this. The oftener we meet the shareholders and consult with them, and the more fully we tell them exactly what we are going to do, the better it will be for the general work and for everyone concerned. I may add that the next general meeting is proposed to be held in about twelve months' time—on the last Tuesday in February, when the accounts up to December 31st this year will have to be considered. But, of course, as soon as the works are opened—which we hope will be some time within the next six or eight

months—we propose to call an extraordinary meeting, and probably we should invite the shareholders to come and view our works. Estimates certainly vary, but I think before the dark days come again we shall have the works open, and the light laid on to a great many houses. That, gentlemen, concludes the business of the general meeting.

The extraordinary general meeting was then called, and the Secretary having read the notice convening it,

The CHAIRMAN said: As I mentioned just now, this is a matter of pure form, to comply with certain requirements of the Stock Exchange. Therefore, if no gentleman has anything to say on the subject, I will propose that the resolution as follows be adopted:—

"*That Article 59 of the Articles of Association of the Company be altered by omitting the following words therefrom, namely:—'Relating to the increase of capital of the Company, the setting aside a reserve fund to meet depreciations of the property of the Company, or any part thereof or concerning or'—such words commencing in the third and ending in the sixth line of such Article.*"

Mr. WATERS seconded the motion, which was carried unanimously.

The CHAIRMAN: We will send round the notice of the confirmatory meeting which is necessary, and that concludes the whole of the business before us. Gentlemen, we must thank you for your attendance to-day.

Mr. ROMER: I beg to propose a vote of thanks to our Chairman for the very explicit information he has given us as to the progress of the works.

Mr. WEST seconded this, and it was carried by acclamation.

The CHAIRMAN having replied, the proceedings terminated.

Telegraph Construction and Maintenance Company (Limited).

The following is the report of the Directors to be submitted to the members at the twenty-sixth ordinary meeting to be held at the offices of the Company, 38, Old Broad-street, E.C., on Tuesday, March 4th, at one o'clock.

The Directors feel that their first duty at this meeting is to express their deep regret at the loss the Company has sustained in the death of their late Chairman, Sir Daniel Gooch, Bart., which feeling they do not doubt will be shared by the proprietors generally, and they desire to lay before them the copy of a resolution which was passed at the Board meeting of October 23, 1889, being the first held after that melancholy event:—"That on the death of their Chairman, Sir Daniel Gooch, which occurred on the 15th instant, the Board of Directors desire to place upon record their high sense of the services rendered by him to the Company during a period extending over 25 years, for 21 of which he was the Chairman, and at the same time to give expression to their own feelings of sincere regret at the loss of an able and upright colleague, for whom they always entertained the highest respect and esteem."

At the same meeting Sir George Elliot, Bart., who has been a member of the Board since the formation of the Company, was unanimously requested to accept the position of its Chairman, and was duly elected. Mr. James Pender has been elected a Director of the Company to fill the vacancy caused by the death of Sir Daniel Gooch.

The accounts for the year show a net profit of £83,746. 12s. 11d., after charging the interest on the Debentures. To this sum must be added £43,376. 14s. 4d. brought forward from last year, making a total of £127,123. 7s. 3d. From this amount is deducted the interim dividend of 5 per cent., paid July 16, 1889, amounting to £22,410, leaving £104,713 7s. 3d. to be dealt with. Of this sum the Directors propose to distribute a dividend of £1. 16s. per share, absorbing £67,230, being at the rate of 15 per cent., and making, with the amount already paid, a total dividend for the year of £2. 8s. per share, or 20 per cent., free of income-tax, leaving £37,483. 7s. 3d. to be carried forward to the next account.

During the past year, the cable factories at East Greenwich and at Wharf-road have been fairly occupied, and the increase in the general business at the latter works shows a marked improvement; a length of about 4,800 miles of telegraph wire has been insulated for submarine cables and land lines.

The Company's steamships have laid cables between the Cape of Good Hope and the Port of Mossamedes, on the western coast of Africa, thus completing the circuit of that Continent; between Java and Western Australia, thus triplicating the Eastern Extension Telegraph Company's lines to Australia; and between Monte Video and Chuy River, on the coast of Uruguay, for the Western and Brazilian Telegraph Company.

Various repairs have also been carried out during the year, on and near the banks of Newfoundland, for the Direct United States and the Anglo-American Telegraph Companies.

The charter of the ss. "Calabria" continued throughout the year, but has since terminated.

The Company's factories at East Greenwich and at Wharf-road are in efficient working order.

The retiring Directors are Sir Thomas Fairbairn, Bart., and Mr. James Pender, who, being eligible, offer themselves for re-election.

The meeting will have to appoint auditors for the ensuing year. Mr. John Gane (Messrs. Gane, Jackson, and Jefferys) who retires, offers himself for re-election. Mr. James Glegg (Messrs. Welton, Jones, and Co.) does not seek re-election. Mr. Patrick Glegg, a member of the same firm, who has always assisted Mr. James Glegg in his audit of the Company's accounts, will offer himself to the shareholders for election.

NEW COMPANIES REGISTERED.

POOLE AND WHITE.—Registered to carry on the business of electric lighting and the supply of appliances in connection with the business and electricity generally, adopting therefor an agreement to be made with Messrs. Poole and White, of Bread-street, Cheapside, for the purchase and taking over of the goodwill, assets, and liabilities of their business upon terms the particulars of which are not specified in the articles of association. Capital, £20,000 in £5 shares. T. G. Poole to be secretary to the company. Borrowing powers not restricted. Registered February 18th, by Saltwell and Tryon, solicitors, 1, Stone-buildings.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended February 21st amounted to £4,637.

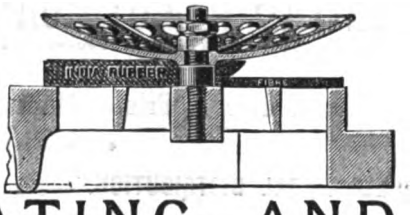
THE MAXIM-WESTON ELECTRIC COMPANY.—Some correspondence has recently appeared in a financial contemporary respecting the position of this Company, to which Mr. T. Blades Gooding has replied as follows:—"In reply to various letters which have from time to time appeared in the London financial papers, calculated to prejudice the interests of this company, I beg to say that the Directors who have retired have not done so because the resources of the Company are exhausted, nor can our resources be truthfully thus described. I do not propose to discuss, in the public press, the financial position of the Company: there will be a shareholders' meeting shortly, at which grievances may be aired and discussed. The Directors have discontinued salaries and fees amounting to nearly £1,000 per annum, and they have now several travellers—responsible men—soliciting orders where not long since they had none. Mr. Swaby now holds no official position in the Company, and has resigned his seat at the Board, which now comprises Mr. John Marks, Mr. Couchman (original Directors), and myself. Mr. Hamilton has resigned the secretarial duties, which are now satisfactorily performed, with no addition to the clerical staff, by Mr. R. Barley. The Board unanimously agreed not to participate in the fees of the retiring Directors, and draw for fees less than one-third of the sum to which they are entitled under the Articles of Association. The Company has established a central station at Dalston, and is now engaged in the manufacture of switches and other electrical appliances, and we hope to largely develop this branch of the business and compete with all other manufacturers for the supply of the whole London and provincial trade. St. Margaret's Mansions are being wired and lighted from our own machinery, and other jobs, too numerous to particularise here, are in hand."

TELEGRAPH CONSTRUCTION AND MAINTENANCE COMPANY (LIMITED).—Notice is given that the transfer books of this Company will be closed from the 24th inst. to the 4th prox., both days inclusive, preparatory to the payment of dividend to all shareholders on the register on the 24th inst.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended February 21st, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited), were £3,523.

NEW VALVE

No Rubber, Percha, or Leather.



One-half the price of Rubber or Metal.

FOR CIRCULATING AND AIR PUMPS.

Unaffected by any Lubricating Oils. Does not Expand in diameter. Feed Water may be worked at any temperature Suitable for any shaped guards. Only one quality manufactured.

"12, John-street, Sunderland, 26th Sept. 1885.

"DEAR SIRS,—In reply to your letter of the 25th inst., the Valves I got from you have done their work well, and ARE AN UNQUALIFIED SUCCESS. I will continue to get them from you as required.—Yours faithfully, JAMES WESTOLL."

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 616.—Vol. XXIV. FRIDAY, MARCH 7, 1890. Price Fourpence.

NOTES.

Upon the Editorial staff of The Electrician this week devolves, perhaps, the most painful duty that men placed in their position can be called upon to perform. They have to announce the untimely death of their esteemed friend and chief, who, after a lingering illness, expired, under his father's roof at Tiverton, on Wednesday night, at the early age of 31. The loss we have sustained will be appreciated even by readers of The Electrician who recognised him only by his writings in these columns; but to those who knew him personally any expressions of regret from us will sound poor indeed—for William Henry Snell was a man, both intellectually and socially, of whom it is hard to speak except in terms of seeming exaggeration. Great as is our loss, the loss sustained by the electrical profession is still greater, for our late Editor was acknowledged among his *confrères* as one of the most brilliant and talented young men of the day.

At the meeting of the Institution of Electrical Engineers on Thursday last week the President announced that Sir David Salomons had made the munificent offer of £1,000 to found a scholarship of £35 per annum, to be held for three years, and to be entirely under the control and at the disposal of the Institution. The Council have gratefully accepted this offer, and have appointed a Committee to consult with Sir David Salomons and settle all details in connection with the scholarship.

Sir David Salomons' generous gift is one which we trust will not long remain the only instance of the kind. The premiums at present annually granted by the Council for Papers read before the Institution carry with them the maximum of honour and the minimum of pecuniary reward. The founding of a premium the intrinsic value of which bore some relation to its prestige would, we think, prove a great addition to the rewards within the gift of the Council.

The recent meeting of the National Electric Light Association at Kansas City, both from the point of view of attendance and of the value of the papers read, seems to have been a very successful gathering. Interesting reports were presented by the Committee on "The Standardization of Potential" and by that on "Harmonizing Insurance and Electric Lighting Interests," and many of the Papers read were of great practical value. An excellent *résumé* of the proceedings will be found in our New York letter.

A large portion of Mr. Sprague's interesting Paper on "Electricity applied to Street Railways," which will be found in another column, is devoted to an ingenious argument proving that it is the telephone companies and not the street railway companies who ought to employ complete metallic circuits. We are glad to note, however, that in spite of the strong position he takes up on this question, Mr. Sprague suggests that "a just compromise but no surrender" should be the motto of street railway companies, on the ground, we suppose, that a fair compromise is less costly than a legal victory. Mr. Sprague's Paper also contains a suggestive sketch of a plan for an electric express railway between New York and Philadelphia.

The Committee appointed at Frankfort-on-Main to inquire into the alternating and direct systems of distribution have issued a report, an abstract of which we publish, from which it appears that the Ganz alternating current motor has a very high efficiency (in some cases 88 per cent.), and maintains itself in synchronism even if the load is suddenly altered 60 per cent. above or below the normal. Although these results are already known to many, their importance is not yet generally realised. The excessive sparking of these motors when starting is a very serious defect. We, however, publish this week a proposed remedy, which appears very promising. Some years ago no direct current dynamo could be obtained which did not give rise to excessive sparking. Most of this has since been got rid of by allowing the armature coils to be short circuited under the brushes before the current through them is reversed. A similar method is now proposed by Zipernowsky, Déri, and Bláthy for the field magnet coils of alternators.

In a communication to the *Philosophical Transactions* on "The Diurnal Variations of Terrestrial Magnetism," Prof. A. Schuster has shown how to calculate the secular variations from the known values of the magnetic potential on the earth's surface. The calculations were compared with observations taken at Lisbon, St. Petersburg, Bombay and Greenwich, from which exceptionally trustworthy data could be obtained. The

Digitized by Google

interest and importance of the comparison consists, not only in the general agreement between the values given by the formula with those actually observed, but also in the fact that it is possible to partially locate the origin of the disturbances. The harmonic method of analysis employed leads to different results, according as the disturbing causes are supposed to be within or without the earth's surface, and the comparison of theory and experiment thus renders it possible to determine whether the main cause of the variations is outside the earth or not.

Prof. SCHUSTER finds that the principal part of the diurnal variation is due to causes outside the earth's surface, and gives good reasons for the supposition that electric currents in the atmosphere are the origin of disturbance. The results of the calculations, however, point to an additional source of variation within the earth's surface, standing in fixed relationship to the main source outside. This seems a natural consequence, since a variation of magnetic potential due to external causes would necessarily be accompanied by currents induced within the earth, and these would in turn give rise to fresh disturbances. The phase and magnitude of these currents lead to definite conclusions about the conducting power of the earth, and one of the most interesting of the results arrived at by Prof. SCHUSTER is that the earth does not behave as a sphere of uniform conductivity, and that the inner parts of the earth must conduct better than the outside crust. When allowance is made for the induced currents within the earth, when supposed to conduct in this way, the agreement between the observed and calculated values of the diurnal variations is exceedingly close.

IN a recent number of the *Comptes Rendus* M. JOUBIN describes some experiments made to determine the magnetic field within a conductor of large section. The conductor consisted of sulphate of copper placed in a vertical glass tube, 18 cm. in diameter, and reposing on a trough of mercury. The upper electrode consisted of a plate of copper placed on the upper surface of the copper sulphate. A small magnet furnished with a mirror was suspended by a silk fibre in the interior of the liquid. When the magnet was placed within a second tube in the axis of the liquid cylinder no force whatever was observed. As the magnet was moved along a radius of the cylindrical conductor the force became greater and greater, and it was found that in the immediate neighbourhood of the surface the action was the same, whether the suspended magnet was inside or outside of the conductor. These results are in conformity with theory, which states that the magnetic force at a point is directly proportional to the distance from the centre when within a circular conductor, and inversely proportional to that distance when outside, the two values coinciding at the surface. We are unaware, however, of any previous tests of magnetic force within the substance of the conductor.

IN the same magazine there is a communication from M. PAUL JANET showing that lines of force remain perfectly continuous in passing from one medium to another, whether the media are magnetised or non-magnetised, conducting or non-conducting. No assumption is made as to the constancy of the relationship between the magnetising force and the resultant magnetisation.

The London Electric Supply Corporation.—We are informed that Lord Crawford has resigned his position as Chairman of this Corporation in favour of Mr. J. S. Forbes.

Verity Cricket and Football Club.—A smoking concert in connection with this club will be held at the "Horse Shoe" Hotel, Tottenham Court-road, at 8 o'clock this evening.

Cathedral Lighting.—The lighting of the interior of Strasburg Cathedral by incandescent lamps has proved highly effective, and the arc lights used outside the building show off the details of the façade exceedingly well.

The Liverpool Electric Supply Company.—On Saturday last a dinner was held at the Adelphi Hotel by the *employés* of the Liverpool Electric Supply Company to celebrate the opening of the Company's new and extensive works at 15, Highfield-street.

Electric Light at the Venice Arsenal. — According to a report just published by the British Vice-Consul at Venice, the project for illuminating the whole Arsenal in accordance with the system adopted at Spezia has been sanctioned by the Italian Government.

Royal Institution.—At the general monthly meeting of this Institution on Monday last the special thanks of the members were returned to Mr. Warren De la Rue for his valuable present of a miniature portrait of his father, the late Dr. Warren De la Rue, F.R.S., M.R.I.

Telephonic Communication with Ships at Anchor.—The Havre Chamber of Commerce is about to carry out some experiments with a view of testing the feasibility of a system of telephonic communication between ships at anchor in the Roads and the local Exchange.

Port Said.—The Egyptian Minister of Public Works has authorised M. Sigmund Fahn to establish a telephone exchange at Port Said. The concession is to last 15 years, with option of purchase by Government at the end of ten. The concession carries no monopoly with it.

Personal.—We regret to hear that Mr. Lant Carpenter has fallen ill from overwork, and has been ordered to take a few weeks' complete rest. It was in consequence of this that Mr. Carpenter was unable to deliver his lecture on "Technical Education" at Toynbee Hall on Saturday last.

The Balloon Society of Great Britain.—The Council having determined to allot an evening a month to lectures and discussions on electrical science, persons desirous of reading Papers or attending the meetings are requested to communicate with the Secretary, 26, Budge-row, Cannon-street, City.

Apparatus for Demagnetising Watches.—A permanent horseshoe magnet enclosed within a box is rotated by means of a handle. To demagnetise a watch it is only necessary to rest it on the lid opposite the poles of the magnet, and to gradually draw it away while the magnet is rapidly rotating.

Devonport and Plymouth.—At a meeting of the Devonport Town Council on Thursday last week a report was read from the Highways and Streets Committee stating that the Devon and Cornwall Electricity Supply Company had decided to abandon the scheme at Devonport and Compton Gifford, and confine their attention to Plymouth.

Chelmsford.—At a meeting of the Town Council on Wednesday last week the Mayor reported that Messrs. Crompton and Co. had fixed Monday, April 14th, as the date on which they will be prepared to take up the contract for lighting the

Digitized by Google

streets of the borough. They will commence "running" next week, however, on their own account.

Wimbledon.—At a meeting of the Local Board on Wednesday night Mr. Holland proposed that the recommendation of the Electric Lighting Committee that the electric light should be adopted forthwith in Wimbledon be agreed to. A lengthy discussion ensued, several speakers objecting to the short notice given, and asserting that the matter was being rushed. The motion was, however, finally adopted by 7 votes to 5.

Railway Companies and the Telephone.—In several towns in Germany and Austria the railway companies have placed their goods yards in connection with the local exchange. By this means consignees are informed of the arrival of their goods, and merchants and shopkeepers are able to obtain any information they may require from the railway company without delay. This extension of the telephone system has proved very popular.

Physical Society.—Mr. Herbert Tomlinson is, we understand, suffering from so severe an indisposition that he will be unable to read his promised Paper upon the Villari Neutral Point in Nickel on Friday, at the next meeting of the Physical Society. On that occasion, in addition to Prof. S. P. Thompson's Paper upon Bertrand's Refractometer, a joint Paper by Prof. Dunstan and Mr. Dymond will deal with an apparatus for the distillation of mercury in a vacuum.

The Direct United States Cable Company (Limited).—This Company notify that they have opened to the public at 40, Hope-street, Glasgow, a new station for the acceptance, transmission, and delivery of American telegrams. The station is centrally situated, and will be found very convenient for American cablers, as the new office will bring the whole of the Company's system within the range of what may be practically termed immediate communication with the Scotch provincial towns.

The Copper Market.—The visible stocks of copper diminished during the month of February by 562 tons. Since the copper crisis at the end of March, 1889, the inroad upon stocks in sight has been nearly 30,000 tons, each month's consumption having exceeded the corresponding supplies. Stocks are now 95,152 tons, contrasted with 124,876 tons at the end of March last. The present price of bars is £47 per ton, compared with £39. 5s. on March 31st, 1889, to which copper had suddenly fallen after touching £100 in September, 1888.

Bridlington Quay.—At a meeting of the Local Board on Saturday last, Dr. Redman said he had had a telegram from Messrs. Laing, Wharton, and Down, stating that as the Board did not accept their tender for lighting the town at the last meeting, they were not now in a position to carry it out, as they had accepted other contracts. The Board resolved that the tender of the Bridlington Gas Company be accepted, and a committee was appointed to consider and report on the best means of lighting by electricity the whole of the district, with power to employ an electrician.

York.—At the last meeting of the Streets and Buildings Committee of the Town Council it was reported that the Yorkshire House-to-House Electric Company and the National Electric Supply Company had decided to withdraw their applications for Provisional Orders. It was also reported that objections to the application of the Corporation for a Provisional Order had been made by the National Telephone Company, the South of England Telephone Company, the Western Counties and South Wales Telephone Company, the North-Eastern Railway Company, and the York Tramways Company.

The Ganz Transformer.—In some tests recently undertaken by a committee specially appointed by the Town Council of Frankfort-on-Main to report on the alternating and direct systems of distribution, the efficiency of Ganz and Co.'s medium sized transformer came out at full load at 95 to 96 per cent., half-load 93 to 94 per cent., quarter-load about 90 per cent., and one-eighth about 80 per cent. An automatic switch by the same company was inspected by the committee, which was to cut out the transformers in groups so as to allow them as far as possible to work at full load.

Wiedemann's Annalen.—In a preface to the XXXIX. volume, Herr Wiedemann gives a short historical sketch of this well-known publication, which was founded in 1790, and has already undergone several changes of name. From 1790 to 1824, the *Annalen* were edited by Gilbert, after whom they were named. From 1824 until 1877, the publication was known as *Poggendorf's Annalen*, and in 1877 it became *Wiedemann's Annalen*. Previous to 1824 the *Annalen* were chiefly comprised of abstracts of foreign scientific articles; under Poggendorf the tone became more German; finally, in 1877, Wiedemann effected a further change by the publication of the monthly supplement.

Electricity at a Paper Factory.—For some time cellulose has been used in the manufacture of paper, but its extended adoption has been retarded by its high price. Dr. Kellner, Director of an Austrian cellulose factory, has, says the *Elektrotechnisches Echo*, succeeded in reducing the cost by the following process:—The shredded wood is put into lead-lined boilers with a 5 per cent solution of common salt, which is electrolysed for three and a-half hours. The nascent chlorine bleaches the wood fibre to a snow-white silky substance. The operation is conducted at a temperature of 126° to 128° Centigrade. The process is expected to have an important effect on the trade, as the paper made from cellulose is of particularly fine texture.

The Electric Light at Co-operative Stores. — Speaking yesterday (Thursday) at the annual general meeting of the shareholders in the Junior Army and Navy Stores, Major-General Hale Wortham (the chairman) stated that during the past year York House (Regent-street) had been fitted with the electric light. He felt sure that the shareholders would approve this proceeding, remembering that the electric light was conducive to a large saving in the cost of painting and decoration; and he might also tell them—what was probably known to many of them—that there was a great deterioration in perishable commodities when gas and similar lights were used. This deterioration did not occur where the electric light was used, to say nothing of the personal comfort of the members and the *employés*.

The Forth Bridge.—The opening of the "biggest engineering show on earth" has been worthily celebrated by our contemporaries, *Engineering* and *Industries*, by the publication of magnificent Forth Bridge numbers. The Paris Exhibition number of *Engineering* will be remembered by many of our readers; and the present one, devoted to the history of the Forth Bridge from its first inception to its completion a few weeks ago, is quite equal to, even if it does not surpass, that enterprising production. The Forth Bridge number of *Engineering* contains 70 pages of excellent descriptive and historical matter, 156 figures, and no less than 19 fine full-page plates. The Special number of *Industries*, although a highly creditable one, is scarcely equal to that of its contemporary, the engravings especially lacking in clearness. This number contains 52 pages, 122 figures, and five plates.

The Consent of Local Authorities to Provisional Orders.—Replying on Monday in the House of Commons to a question asked by Mr. R. K. Causton, Sir Michael Hicks-Beach informed the House that the Board of Trade had not determined not to proceed with any applications for Provisional Orders to supply electricity, if the local authorities refused their consent. In view of the Sessional Orders of Parliament the Board of Trade informed the promoters of Provisional Orders that they should not proceed with applications unless the consent of the local authority was produced by February 25th. Where, however, there was anything in a case to cause the promoters to request the Board of Trade to dispense with such consent their application would be carefully considered, and if there appeared to be exceptional circumstances connected with the refusal of the local authority an inquiry would be held.

Central London Railway Bill.—No fewer than 31 separate petitioners will appear in opposition to this Bill. Among the opponents are the Corporation of London, the Commissioners

Digitized by Google

of Sewers, the London County Council, the St. Giles's District Board of Works, and the vestries of St. James's, Westminster, St. George's, Hanover-square, Paddington, and Marylebone, the Gas Light and Coke Company, the Grand Junction, the East London, and the New River Water Companies, the Metropolitan, Metropolitan District, and the London, Chatham, and Dover Railway Companies. Among the other petitions are two from the owners and occupiers of property along the proposed line of railway, two from owners and occupiers of property in Oxford-street and Bayswater-road, two from the Mercers' and Skinners' Companies, and ten from landowners, including the Duke of Westminster, Viscount Portman, and the Ecclesiastical Commissioners. The remaining petitioners are the Gresham and Equitable Assurance Societies, the Metropolitan Electric Supply Company, the London Hydraulic Company, the Union Bank of London, and the City of London and Southwark Subway Company.

Curious Effect of Atmospheric Electricity on an Underground Telegraph Wire.—In a recent number of *La Lumière Electrique*, M. P. Marcillac, in commenting on some earth phenomena recently observed by Signor Palmieri, relates the following interesting incident connected with subterranean telegraph wires:—In 1883, while fault finding, M. Marcillac found himself in a wood between Marseilles and Toulon. The weather was fine and he was in telephonic communication with Marseilles by means of some excellent Siemens apparatus. The telephone was interposed in a circuit formed by two underground wires, and there was, strictly speaking, no earth and no overhead section. The weather suddenly clouded over, and a violent crackling was heard in the telephone. Rain soon fell, and obliged the party to seek refuge in their tents. At about three kilometres distance M. Marcillac noticed a grey-coloured cloud, shaped like an inverted cone, oscillating in a most extraordinary manner. Each oscillation of the cloud corresponded to a violent crackling in the telephone. The noise of the thunder prevented conversation, and a field Morse apparatus was rapidly installed to maintain communication with Marseilles. The effect of the oscillating cloud continued and caused the tongue of the Morse apparatus to be attracted with such force that in order not to sacrifice his apparatus M Marcillac had to put the line to earth. The rain fell in torrents for a few minutes, after which the phenomena ceased. M. Marcillac points out that this was not a question of earth currents, but of induction experienced in a carefully insulated subterranean line.

Brighton.—A special meeting of the Town Council was held on Monday last to consider the reports from the Lighting Committee and the Works Committee relative to the purchase of a site for a central lighting station, and the report of Mr. Shoolbred. After a discussion lasting over five hours, the various resolutions proposed were carried by large majorities. It was resolved to purchase the site offered by Messrs. Vallance, Catt and Co., for the sum of £7,000, to appoint Mr. Shoolbred electrical engineer, to accept the plans and specifications of Mr. Shoolbred, and to instruct the Town Clerk to advertise for tenders. The special resolution of the Council of January 23rd, adopting the extended area, was also passed.—The following are some of the questions put to Mr. Crompton by the Committee, together with his replies to the same, published in his report, referred to in our last issue:—(1) On the best system of generating and distributing the electric current in Brighton; (2) the site or sites at which the electricity can be most conveniently generated; (3) on the cost of plant; (4) on the cost of working the plant; (5) on the use of the Corporation Ash-yard as a site for a central station, with the object in view of utilising a portion of the town refuse as fuel; and (6) the comparative advantages of steam and gas engines for working the generating plant.—(1) the storage system; (2) either the site in Black Lion-street or that in Church-street; (3) £30,000 for plant and mains to supply 5,000 16 candle-power lamps lighted simultaneously; (4) the cost of producing a unit is estimated at 8·2d. if 100,000 units are sold, and at 3·6d. if 400,000 units are sold; (5) experiments to determine what is the calorific value of the town refuse ought to be carried out; (6) Mr. Crompton advises steam engines.

Electric Bills in Parliament.—The City of London and Southwark Subway Bill was read a second time in the House of Commons on Friday last. The following additional petitions against Private Bills have been deposited in the Private Bill Office:—Against the London Subways and Overhead Wires Bill: By the Conservators of the River Thames, the Great Western Railway Company, the Westminster Electric Supply Corporation, the Great Eastern Railway Company, the Commissioners of Sewers, the City of London and Southwark Subway Company, the London and North-Western Railway Company, the Wandsworth and Putney Gaslight and Coke Company, the Honourable Society of the Inner Temple, the Vestries of Hammersmith and Kensington; the South-Eastern, Midland, Great Northern, Metropolitan District, London, Chatham, and Dover, London and South-Western, Metropolitan, and East London Railway Companies; the London Hydraulic Power Company, Corporation of London, Commercial Gas Company, National Telephone Company, and the House-to-House Electric Light Supply Company, and others—in all 28 petitions. A petition in favour of the Bill has been deposited by the Vestry of Bermondsey. Against the City of London Electric Lighting Bill: By the Laing, Wharton, and Down Construction Syndicate, the City Commissioners of Sewers, the Brush Electrical Engineering Company, the District, the Metropolitan, and the London, Chatham, and Dover Railway Companies. Against the City of London and Southwark Subway Bill: By the London, Chatham, and Dover Railway Company. The Committee of Selection have held a meeting and formed the following Bills in groups:—The London Subways and Overhead Wires in Group A; and the City of London Electric Lighting Bill, the St. Martin-in-the-Fields Electric Lighting Bill, and the Strand Electric Lighting Bill in Group F. At a meeting of the General Committee on Railway and Canal Bills, the Central London Railway Bill and the City of London and Southwark Subway Bill were put into Group I.

Electricity in Warfare.—In a lecture on "Electricity in Warfare" recently delivered before the Franklin Institute, Lieut. Bradley A. Fiske, of the United States Navy, said, among other things, that it was in the modern warship that electricity had its broadest field: in no other equal space could there anywhere be found so many, so various, and so important forms of apparatus. In the United States cruiser "Chicago" one of the eight-inch guns was trained by an electric motor, and with gratifying results. The gun could be trained much quicker than by hand: but that was not the real element of superiority. The real element was the absolute control possessed by the gun captain. The problem of supplying ammunition with sufficient rapidity to carry on a modern engagement was one of the most important problems pressing for solution. The ammunition hoist now on board the "Atlanta" was a step in this direction, furnishing as it did a means for raising ammunition to the deck quicker than by hand, with greater safety and with fewer men. In this hoist, as in the gun training apparatus, the idea was carried out of making the electric motor follow the motions of the operator's hands, both in direction and speed. The operation of turning a wheel or crank caused the switch to start the motor in a certain direction. If the operator began to decrease the speed with which he turned the crank, the motor would overtake him, and would partially close the switch: the motor would therefore lower its speed; whereas, if the operator increased his speed of movement, the switch would thereby be opened further, and the motor would go faster. The advantage of this plan in the case of an ammunition hoist was apparent, since the entire time required on board of the "Atlanta" to raise a 250lb. shell was 9½ seconds. Now, this interval gave a man very little time to think, and if the ordinary arbitrary movements for starting and stopping motors were employed, an accident would some day result from the wrong movement being made. Furthermore, if a shot disabled the motor or its connections, everything stopped, and the shell simply stayed where it was. This was a much better thing for it to do than to violently descend, or be forced up against the deck overhead, as would happen with any other device now known.

MAGNETISM IN IRON AND OTHER METALS.*—VIII.

BY PROF. J. A. EWING, F.R.S.

(*Continued from page 417.*)

§ 44. To Find the Directing Force at the Magnetometer.—In measuring magnetism by the magnetometric method, we must know the force F_1 which directs the needle when it hangs in the undeflected position. Even when no special directing magnets are used, it is not safe to assume that F_1 is identical in value with the horizontal component of terrestrial magnetism, for the earth's field is often seriously altered within a room by the magnetic influence of iron pipes, beams, and so forth. So long as these disturbing bodies are not liable to be moved about, or to have their temperature much altered, their effect in modifying the magnetic field—though it may be considerable—will be nearly constant, and in that case an occasional measurement of F_1 will suffice. If there are iron heating pipes or stoves in the neighbourhood, the utmost care is necessary to see that F_1 does not vary. Fixed masses of iron at the atmospheric temperature are not a very objectionable feature in a magnetic laboratory; but it is difficult to exaggerate the nuisance that may be caused by an iron stove or steam-pipe liable to quick changes of temperature.

We may make an entirely independent measurement of F_1, following the well-known method which is used in measuring the horizontal component of the earth's field,† and taking care to swing the deflecting magnet in the place where the magnetometer is to stand.

But in general all that is required is to go through as much of this process as will serve to find the *relative* values of F_1 and the horizontal field F at a place where there is no local magnetic disturbance. In most places F is sufficiently well known from the results of recent magnetic surveys, so that the absolute value of F_1 may be deduced when we know the ratio it bears to F.

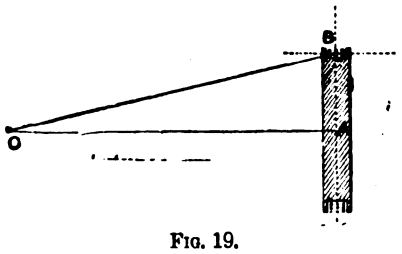

FIG. 19.

To compare the two, take a short straight piece of permanently magnetised steel wire, and suspend it to hang horizontally within a glass vessel by a little cradle and a silk fibre 3in. or 4in. long attached to the cover, so that it is free to swing. Put it where the magnetometer is to stand, and set it swinging torsionally (*not* pendulum fashion). This is most easily done by bringing near it a bar magnet, and then drawing that away, keeping the two poles of the bar equally distant from the hanging wire. When the swings have subsided so that the motion is no more than 5deg. or so to either side, begin to count them. Note with a watch the instant at which the magnet swings past its middle position towards one side, count 30 or 40 complete swings, and again note the time the magnet swings past its middle position towards the same side. Find in this way the time t_1 (in seconds) required for one complete swing. Then take the swinging magnet to some place (outside) where there is nothing to interfere with the terrestrial magnetic field, and repeat the counting there to find the time that is required to make one complete swing when the only directing force is the horizontal component F of the earth's field. The directing force is inversely proportional to the square of the period of swinging, hence the directing force at the place where the swings were first counted

$$F_1 = \frac{F t_1^2}{t^2}.$$

When the magnetometer is furnished with a "compensating coil" (§ 41) the following is a good way to find F_1. Remove the magnetising solenoid and set the compensating coil at a known distance, O A (Fig. 19), behind the magnetometer. Pass a known current, C,* through it and observe the deflection θ of the magnetometer. A B is the mean radius of the coil, and O A is measured to the middle of its width. Let q be the number of turns in the coil; then the deflecting force which is produced at O by the current in the coil is

$$\frac{2\pi C q \overline{A B}^2}{(\overline{O A}^2 + \overline{A B}^2)^{\frac{3}{2}}}, \text{ or } \frac{2\pi C q \overline{A B}^2}{\overline{O B}^3};$$

and, since this is equal to $F_1 \tan\theta$, we have

$$F_1 = \frac{2\pi C q \overline{A B}^2}{\overline{O B}^3 \tan\theta}.$$

§ 45. Example of a Test of Iron by the Magnetometric Method.—Before proceeding to describe the ballistic method of measuring magnetisation, it may be useful to illustrate the magnetometric method by giving the particulars of an actual experiment on a piece of wrought-iron wire.

The diameter of the wire (d) was 0·077 cm. The length of the specimen was 30·5 cms., or 400 diameters. It was annealed or softened before the test by drawing it through a lamp flame so slowly that each part of the length, in succession, was heated to bright redness and then cooled slowly as it passed away from the flame. The "one-pole" arrangement (§ 40) was adopted. A preliminary trial showed that the effective "poles" lay very near the ends of the wire. The upper one was set at a distance (O Q) of 10 cms. behind the magnetometer; the distance O Q′ to the lower pole was 31 cms.

The directing force at the magnetometer F_1 was 0·299 in C.-G.-S. units. The deflections were read in millimetres, and the scale was set at a distance of 1 metre from the magnetometer. Hence one scale division of deflection corresponds to a value of $\frac{1}{2000}$ for θ or $\tan\theta$.

Substituting these values in the expression of § 40,

$$I = \frac{4.\overline{O Q}^2 . F_1 \tan\theta}{\pi d^2 \left\{1 - \left(\frac{O Q}{O Q'}\right)^3\right\}},$$

we have I for one scale division of magnetometer deflection

$$= \frac{4 \times 10^2 \times 0{\cdot}299}{3{\cdot}1416 \times \overline{0{\cdot}077}^2 \times 0{\cdot}9665 \times 2000} = 3{\cdot}32.$$

Again, the magnetising solenoid contained 69 turns per centimetre of its length. Its magnetising force for one ampere of current was, therefore,

$$\frac{4\pi \times 69}{10} = 86{\cdot}7.$$

The current was measured by a mirror galvanometer, which was found to give a deflection of 575 scale divisions, with a current of 0·235 amperes. This corresponds to 0·000408 amperes per scale division. Hence the magnetising force for one scale division of the galvanometer was

$$86{\cdot}7 \times {\cdot}000408 = 0{\cdot}0354.$$

After the independent current (in a separate solenoid) which was required to balance the vertical component of the earth's force had been adjusted, the process of demagnetising by reversals was gone through to wipe out any traces of magnetism the wire might have acquired in handling. Readings of the magnetometer and galvanometer were then taken, while the current was slowly increased step by step from zero till the magnetic force reached a value of 22·27 units. Then the current was slowly and step by step reduced to zero, the magnetism retained by the specimen being observed at each stage, and then a negative current was applied, giving a reversed magnetic force, which was slowly increased until the residual magnetism began to become reversed. The results of the experiment are stated in the table on following page:—

* All rights are reserved.

† Full directions for the determination of the horizontal component of the earth's field will be found in Prof. A. Gray's "Absolute Measurements in Electricity and Magnetism."

*Here, as elsewhere, the current is expressed in absolute electro-magnetic (C.-G.-S.) units. If its value is known in amperes we must divide the number of amperes by 10 to find C.

− 71	−2·51	70	232
− 81	−2·87	−12	−40

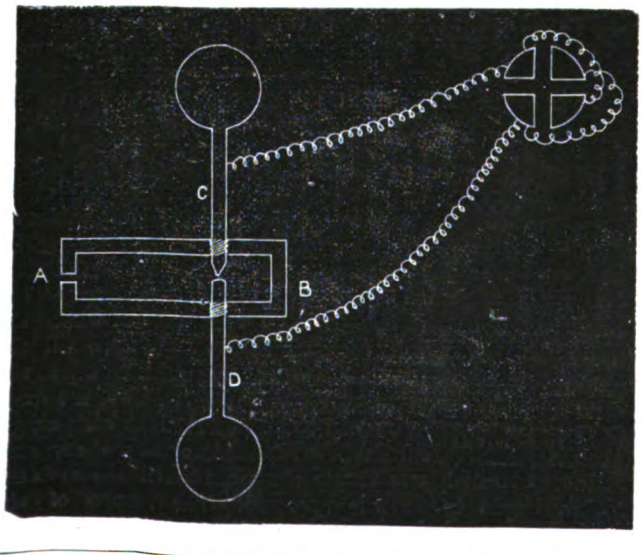
Column 1 gives the observed galvanometer deflections, and column 2 the magnetising force calculated from them. This is produced by the solenoid; in the notation of § 25 it is H′, and is a little greater than the true magnetic force H, which is diminished by the action of the ends of the specimen when it becomes magnetised. Column 3 gives the observed magnetometer deflections (due to the wire alone), and column 4 gives values of I calculated from them.

(*To be continued.*)

AN ELECTRICAL OSCILLATION DETECTOR.*

BY PROF. JAMES BLYTH, M.A.

The object of the note was to describe a form of oscillation detector which the author had found convenient in repeating the experiments of Hertz, Lodge, and others, especially as it obviated the necessity of working in a dark room. In consists simply in a thick-walled tube of vulcanite (*see* Figure), about 10in. long and ⅜in. bore, closed at one end B, and provided with a peep-hole at the other end A. Near the one end B two stout copper wires, C and D, are screwed through the walls of the tube, so as to be diametrically opposite, and in the same straight line. The end of the wire C has a long conical point, and is carefully polished, while the end of D is rounded and also polished. The other ends of both wires terminate in light copper balls. Each wire is about a foot long, and the diameter of the balls about three inches. By means of the projecting vulcanite tube, the detector can be easily fixed in any position by clamping in a retort-stand.



When the oscillator is at work, and the point inside the tube properly adjusted, a bright star-like appearance is seen when the eye is applied to the peep-hole, and thus a dark room is not necessary. For demonstration to an audience, the wires C and D are connected to the electrodes of a quadrant electrometer, and it is observed that whenever sparks are seen in the tube the spot of light moves erratically over the scale, becoming always steady when the sparks cease. By this arrangement the author had been able to repeat most of Hertz' experiments, and showed a few of the more characteristic of them to the meeting.

* Communicated to the Philosophical Society of Glasgow, January 8th 1890.

ELECTRICITY AS APPLIED TO STREET RAILWAYS.*

BY FRANK J. SPRAGUE.

Scarcely fifteen years, a period of time yet within the memory of the youngest of us, have passed since the beginning of a new era, the era of the transmission of energy for light, power, and the reproduction of speech. Of the progress of the first I need not speak, for the delegates of this Convention are well cognisant of its history and the advance it has made within that time. The spread of the telephone to nearly every town and hamlet in the fourteen years since it was exhibited as a scientific toy at Philadelphia, and the financial success of the parent company, are facts continually before your minds or ringing in your ears. But that industry, the transmission of electricity for power, with its possibilities of all kinds, is of very recent development. Six years ago there were scarcely a hundred electric motors in operation in the United States for any purpose. To-day there are no less than 15,000 motors in use, applied to not less than 200 different industries; and an industrial revolution is taking place equalling, if not surpassing, in importance that attending the introduction of the steam engine, and marvellous in the rapidity of its growth. It is not my purpose to dwell at length upon the subject of the transmission of power by electricity in its general application, but to touch upon one branch only, that of railway work, reviewing very briefly the development in the United States, pointing out the salient features of successful operation, noting what has been already accomplished, and, after some remarks upon the legal questions which have arisen, considering the possibilities of the future.

The first line which was established in the United States for actual commercial service was a suburban line of two miles in length, built by Mr. Daft, just outside of Baltimore, in the latter part of 1885, using a central rail. Other lines were established by Mr. Vanderpoele in various parts of the country, using the single and double trolley systems, with the trolley travelling upon and carried by the wire, and connected to the car by a flexible cable. Of the more recent work three classes demand attention, one being the system of independent units operated by the storage battery, and the other two being direct systems of supply, one underground the other overhead.

There is something exceedingly attractive in the proposed application of storage batteries to the propulsion of cars. To be able to conveniently store up a large amount of energy in a box, put it aboard of a car, carry it around with us, and take from it a greater or less amount of work, offers, when practicable, a solution of the street-car problem for which we are all devoutly hopeful. But look at it commercially. The storage battery is still a long way from being a serious competitor of the direct source of supply. True, great improvements have been made in it; but these improvements have not very much altered its character, or the weight which is necessary, or the care which must be exercised in getting an economical return from the battery. These improvements have made it possible to take a heavier charge from the battery without producing

Digitized by Google

buckling, have made a rougher usage of the battery mechanically possible, and have in some instances greatly reduced its cost of manufacture, so that the element of maintenance is a less serious one than it was a year or two ago; but the capacity of the battery, while it has been somewhat increased, remains such that it is still necessary to have about 3,500 pounds to propel an ordinary street car. This means an excessive weight. It takes up space, and is a serious extra weight to be carried around. It requires frequent shifting, and its capacity as well as discharge rate are so limited that it is simply impossible to work such a battery upon grades which are at all severe. I believe it is possible with care to operate a storage battery on grades not exceeding, say, 4 per cent., and with limited speed and daily mileage at an expense about equal to that of horses, or a little less; but still at about double the expense which is necessary upon a suitably erected and properly operated overhead system. Nowhere in the United States, that I am aware of, is there serious storage-battery work being done at the present moment. The nearest attempt was where recent experiments were made on the Madison Avenue line, New York City, where about a dozen cars were being run until 8 o'clock in the evening; but owing to legal complications, only two cars are now running there; with what daily mileage I do not know. But nowhere is the work done at all equivalent to what is constantly practised on the overhead line. On that service motor-cars start out at 5 or 6 o'clock in the morning, and run until midnight. Many cars make 150 or 160 miles a day, and some cars have even made 180 and 190 miles a day. Half of this for storage-battery work is good duty, but it is not up to the demands which street-railway managers make, and until radical improvements are made in it, the field of application will be limited.

The conduit system of direct supply has been attempted in several places, notably at Denver, Cleveland, Allegheny City and Boston; but at all the places mentioned these experiments have proved disastrous and have been abandoned, save the short section at Allegheny City. In England, the Blackpool line under special conditions has been, I believe, fairly successful, and at Budapest the Messrs. Siemens have a conduit system in successful operation. There, however, the drainage is very perfect, and in addition a man is detailed for given sections of the track, and is continually employed in patrolling his section and clearing it out. Assuming good sewerage, the conduit can unquestionably be made to work. It becomes then a question of cost; but for general application, especially in view of the fact that most of our cities do not have a sewerage system which can take care of the street drainage, the expense is prohibitory save on large systems under exceptionable conditions. I look forward to the time when many existing well-constructed and well-drained cable conduits will become electrical conduits, and electricity will then score another victory.

The system, however, which has made such a marked advance is the single trolley overhead system, with universally flexible underneath contact, and this has been the growth of the past two and a-half years. I think I can fairly claim for the Sprague Company the pioneer place in this development; but the commercial development on the lines it laid down has been with great energy pushed forward, principally by both it and the Thomson-Houston Company. The first work done by the Sprague Company, other than experimental work on the elevated railroads, was made but a short distance from this city. A single car was started in 1887 on the Union Passenger Railway Company's line in St. Joseph, with a small 7½ horse-power motor, single-geared, and adapted to run at a very high speed on a suburban extension. It is a matter of interest that that line has seen nearly every change made in the system. Its lines have been extended twice, and it has both the old-style motors and the more modern equipments. But all the work done on that line in 1887 was, it may be said, purely experimental; and it was not until February 2, 1888, that the Richmond road was officially opened to the public. I speak of this road not so much because of my personal interest in it, but because it marked an era in the development of electric railways. A radical departure was made from the work which had been done prior to that time, not only in the amount and extent of the system equipped and the number of the machines operated, but also in the disposition and control of the machines, the system of overhead wiring, and the method of getting the current from the wire. The characteristics of that line are now pretty well known. It was a road of about 12 miles in length, with 30 curves, some of them of exceedingly short radius, with grades running as high as 10 per cent., and with a road-bed utterly unfit for the traffic which it had to support. The equipment was for 40 cars, requiring 80 machines, and was to be operated from one central station. When first proposed the attempt was looked upon with a good deal of ridicule, not only by street-railway men but by electricians themselves. The street-railway men thought that the ordinary condition of street-car service would make it impossible for a self-propeller car to ascend a grade exceeding 5 or 6 per cent., and as for attempting a 10 per cent. grade, that was out of the bounds of reason. As regards the electrical problem, the motors, instead of being placed on the car body flexibly, connected by chain gearing or belts to the axles, were placed underneath the car, and flexibly and concentrically geared to the axles. They were uncovered and exposed to the mud and moisture, and to all the loose combinations which might accumulate in the street. They were built to run on a 400-volt grounded circuit, and to run in either direction with fixed brushes. Insanity was a mild term to designate the mental condition of one who made these proposals. The motor man was confined to his ordinary platform, and the regulating devices there situated. A wire of one-fifth of an inch in diameter was extended over the track, and supplied at intervals of its length by a wire carried alongside the street where the strain upon the poles was least, and this main conductor was supplied at three or four central points by feeders, which came from the central station. The current, moreover, was taken from this wire, not by a travelling carriage upon the wire, flexibly connected with the car, but by an arm reaching upward and pressing underneath the wire. This contact arm, which is now technically known as the trolley pole, was placed in the centre of the car and had a universal movement, resisting up and down movement sufficiently to make a good contact with the wire, but at the same time free to follow all vertical deflections. In addition it had a lateral movement of considerable reach, offering little opposition to any side-deflections by the wire itself. Well, Richmond has passed into history. It has had its vicissitudes—it has had its victory as well. But it remains, with all its crudities, and with all the accidents which have marked its career, as the one great step in advance, whose features, in the main, have been followed in almost all the recent electric railways. Machines have been made larger; they have been made mechanically and electrically more perfect; changes of detail have been frequent, but most of the characteristic features there outlined mark to-day nearly every electrical railway which is either in operation, in process of construction, or under contract.

Taking our work alone, and that of 1887 as a basis, in 1888 it was trebled. The work of 1888 was quintupled in 1889. As to what it will be in 1890 I will not hazard a guess. Two years ago it was in an experimental stage, and it was difficult to get a dollar for investment; to-day it demands the best thought and the most active energies of two great corporations and a number of smaller ones. The contracts for electrical equipments involve larger amounts than almost any other electrical enterprise. The business done in this year will probably be not less than $6,000,000. Every street railway in the United States is watching with eager eyes the developments of the rival electrical interests. The advocates of the cable system are on the defensive. The advocates of the electric system are reliant and aggressive. Its flexibility, the ease with which it is extended, its adaptability to various conditions of service, its freedom from a long continued break-down, the marvellous advances which have been made in perfecting its apparatus, all ensure its supremacy. As illustrating the progress of electric railways, I may state that there are about 130 towns in the United States with one or more electric railways in operation, construction, or under contract, and that these roads comprise about 1,500 miles of track, equipped with about 1,700 motor cars, requiring 3,000 motors of an aggregate capacity of 45,000 horse-power.

As regards danger, the electric car is the safest possible vehicle, because of the remarkable facility of control, and as to the objections to the overhead line on the score of danger which have been raised, sometimes by the authorities, and which have been cited by the telephone interests, they are, we may safely say, imaginary rather than real. Some two years and a-half ago I settled upon 400 volts as a fairly satisfactory standard of potential for which the motor for street-railway service should be built, allowing about 10 per cent. drop in the distribution on the line, making the potential in the station about 440 to 445 volts. In some cases, where dealing with heavy work on extended lines and small conductors, we have raised the potential at the motors to about 450 volts, making no change whatever in the machine, and have run the central station at 480 to 500 volts. There are in the United States about 80 electric railways in operation. Almost every *employé* of the contracting companies, and a great many *employés* of the railway companies themselves, including not only the linemen, and those whose business it is to work upon the electrical equipment, but also the conductors and drivers, have received shocks from these lines, of greater or less duration, and under almost every possible condition. Yet, in no instance which ever came under my observation, or of which we have any reliable record, has serious injury resulted from the shock of the current itself. When we consider that these shocks have occurred to persons of all ages, and of all physical conditions, and for varying periods, the experience seems to be quite ample to warrant the assertion that, as ordinarily constructed, a constant-potential circuit of 500 volts is not dangerous to human life; and we can dismiss that question.

Reviewing the work of the past two years, that which was promised for electricity has been in the main entirely fulfilled. It has proved itself capable of doing the most extraordinary work under

Digitized by Google

the most unfavourable conditions. Grades of 12½ per cent., and more recently of 14 per cent., have been ascended with loaded cars. Grades three miles long, varying from 4 to 8 per cent., have been ascended by a motor-car pulling a tow-car. It has done this work where it would have been impossible to have done it by horses. It has enabled the running speed of cars to be increased even in crowded cities 50 per cent.; and on suburban routes speeds of 20 miles or more have been made. Experimental runs of 30 miles an hour on the ordinary street car with the narrow flange wheel have been attained; and on special experiments a speed of nearly 150 miles an hour has been attained for a short distance. The electric car has shown that it can run faster on both up and down grades; that it can be got under way and stopped more quickly than a horse car; that with any given number of cars the mileage has been increased, and at the same time intervals made with a less number of cars. Many cars have made from 180 to 190 miles in one day. Horse space having been saved, the equipments occupy a third less space; and this fact, coupled with the ability to back when necessary, and again quickly gain headway, has enabled an electric railway car in crowded and narrow streets to work its passage where a horse car would be at a dead standstill. Not only has the possibility of running down grade faster been established, but that possibility with a high degree of safety, because in the event of losing control of a car by the brakes, the instant reversal of the motor will bring the car to a standstill. This has frequently been the experience, and in one case which was recently reported to us the inspector stated that a car was going nearly 35 miles an hour on the down grade before the driver attempted to reverse his machine; but when he did reverse it he brought his car to a standstill with the loss of only one gear. Making due allowance for the possible excitement of the inspector, I think the car was moving at least 25 miles an hour when the reversal took place.

The cost of operation has proved entirely satisfactory, and my early claim has been substantiated. In a Paper read before the American Institute of Electrical Engineers in August, 1888, and also in some earlier communications, I made an estimate as to the expense of operating a thirty-car road, dividing these operating expenses under two heads: (1) those belonging to the central station; and (2) what may be called the road operating expenses; the sum of the two constituting the total cost of motive power. In making this estimate I used extreme care, and while preserving its accuracy, made every reasonable allowance that I thought necessary. The conclusion at which I arrived in the estimate under the conditions there given was, that the total cost of motive power per car mile should not exceed 4 3-10c. each, and this included everything except executive and salary expenses, taxes and insurance, and other matter not connected with motive power. I also stated that this was about 40 per cent. of the cost of operating by horses for the same number of cars and under the same conditions. My estimate was then considered altogether too liberal in favour of electricity. Without going into details, I may state that the most reliable possible records of roads, under every possible condition of service, bear out the claims that I then made as to the economical operation by electricity. I have the records of only a portion of the roads which we have equipped. Some roads see fit to make public these records; others, and with a good show of reason, do not care to do so because of the feeling that municipal bodies in considering the granting of franchises will not look at the increased cost of investment, but, ignoring the manifold advantages to be gained by the introduction of electricity, for the public as well as for the company, are inclined to make unreasonable demands in the way of the reduction of fares, or require unnecessary and unprofitable extensions of lines. But suffice it to say that careful investigation will convince any candid man that the economic claim has been entirely supported; and the best evidence of it is in the rapid adoption of this method of propulsion.

A few remarks may be in place relating to the interferences with other established interests which this new application of electricity has developed. There have been, long before electric railways became at all common, conflicts of a more or less limited nature between the electric lighting and telephone interests. In the early days of electric lighting, and more particularly in that branch known as constant-potential distribution, an attempt was made to use the earth for one-half of the circuit, precisely as was done and has been done for years in telegraphy. Practical experience, however, demonstrated that this was a mistake where incandescent lights were concerned, and it is manifestly a mistake where arc lights and high potentials are used. The objections on the constant-potential incandescent circuit were pertinent because of the liability of fire in the buildings where the ground circuit was used; and the element of personal danger very quickly put an end to an attempt to use a ground circuit for an arc light system. The same cautionary reasons applicable to these two classes of industries do not, however, apply to overhead electric railway systems. The electric railway circuit is purely an external circuit. Its derivations are through the cars which it supplies. It is led into no dwelling; its fixtures are not within the ordinary reach of any being. It is carried in the open air, in full view, in the most direct possible lines, and with only such supports as are necessary to make its construction safe and to keep it in alignment. The whole construction of an overhead electrical system is materially simplified, and, in my opinion, made, mechanically as well as electrically, far safer by the adoption of a single wire, using the rails as a return circuit. The practical proof of the wisdom of this decision is the fact that about 90 per cent. of all the electric railways, either in operation, construction, or under contract in the United States, use only the single wire underneath-contact. It scarcely seems necessary at this stage to go into the defence of this system. Its simplicity, the lightness of construction, the symmetry of outline, the size and strength of the poles, the fewness of the supports, the simplicity of all curve work, turn-outs, crossings, and sidings, and especially of all switch work and switch operations, are so manifest that elaboration of these features is unnecessary. The use of the grounded circuit has unquestionably interfered with another and widespread application of the use of electricity, and that is the operation of telephones which likewise use the grounded circuit. So long as electric railways were in an experimental stage, running, perhaps, in suburban districts, out of the way of telephone circuits, little or no attention was paid by telephone companies to their existence. The strides which have been made in the past two years and a-half, bringing the railway system into the very heart of towns and cities and into the forefront as a commercial enterprise, the rapid increase in the extent and use of the telephone system, have brought the two interests in direct conflict, which conflict is solely because of their common use of earth.

The claim of the telephone company in brief is, that, by right of prior occupation and because of their vested interests, no electric railway or other circuit shall so use the earth if interfering with their lines in any way. Their claim is far-reaching; it is of the broadest possible character, and, strictly interpreted, is an exclusive claim to the use of the earth for transmitting energy by electricity. That there is an interference with the telephone circuits by an electric railway circuit is undeniable, and the interference is one which is annoying. The character of the interference is two-fold—the trouble arises from induction or leakage. The relative amount of these two interferences has been variously stated. On the part of the telephone company, it is admitted that leakage is a source of trouble. They also admit that the use of any metallic return circuit—it matters not what, whether it be an individual circuit for each telephone, or a common metallic return for all the telephones—will obviate this, or most of it. Even this much is admitted by the telephone interests with a great deal of hesitation, despite its perfectly apparent truth. But they go further. They claim that this is not the principal cause of trouble, but that most of it is due to induction, and that if a return metallic circuit overhead were put up by the railway company—that is, if a double trolley system were used—then the telephone troubles would all cease. The various attempts they have made in the Courts have been with a view to either compelling the railway companies to cease operations or to so change and erect their entire system as to abolish the use of the single trolley and erect in its place the double trolley system, or, on the other hand, to compel the electric railway company to pay for the necessary changes required in the telephone circuit to avoid the interference. No sooner was this issue presented than it was promptly met by the railway interests which I represent.

Now, what are the facts? First, as I have stated, there is unquestionably an interference between the electric railway and the telephone service; but of the character of this interference, it seems to me that no intelligent man who honestly makes an investigation seeking after truth and truth only, and not biased by the commercial interests which have retained him, can have any reasonable doubt. The assertions made by the telephone interests leave little room for exaggeration on their part. Not only has the character of the interference been misrepresented, but the costs of any changes made necessary on the part of the telephone company to avoid trouble, or on the part of the railway company to change over its system, have been grossly mis-stated. As a matter of fact, the trouble from induction is of the very slightest character, and that must be patent to any one who is familiar with this particular electrical action. Generally the trolley wire is situated in the middle of the street, anywhere from twenty to thirty or forty feet away from the telephone lines. It rarely runs parallel to them except for a comparatively short distance—possibly two, or even three miles, but more often less. The current used upon this wire is not of that character which distinguishes some of the arc light circuits, but is of more or less even flow, and the abrupt and large changes due to change of load on the motor are comparatively infrequent. There is a very small change due to the variation of resistance of the armature of the motor, because of the different relative positions of the commutator blocks under the brushes, and there is likewise a variation due to the slight but rapid changes of counter-electromotive force set up by the motor when running. But although

Digitized by Google

these changes can be detected inductively, provided the conditions are favourable—for instance, if both the telephone and railway circuit were wound around a common bar of iron—the character of the disturbance is not so serious as to preclude conversation. But the trouble which does really become pronounced is that which is due to the actual differences of potential which exists on different parts of the track circuit—in other words, at the terminals of the grounded telephone circuit. There is discharged into the earth, as I have pointed out, a slightly varying current. It may be at some point considerably removed from the station and in close proximity to the ground terminal of a telephone whose exchange is likewise grounded at another point much nearer, electrically, to the station than the point of discharge. The current reaching the rail has to travel back to the station, partly by the rails and partly by the earth. Both offer more or less resistance, and there is an actual difference of potential between the point of discharge and the station, rising at times to as high as 20 or 30 volts; but it is, of course, a variable potential, and the current which flows over that path is one which varies in its character. Having discharged the current in the earth, there is absolutely no limit to its diffusion. We desire, of course, that it should return by the rails, but no boundary can be placed upon it. The shortest geographical line between two points may be a thousand feet. The paths of the current between these two points may be anything from a thousand feet to fifty thousand or more. But precisely as the rail current is thus disseminated or diffused in its return paths, so also is the telephone current. True, it is only a current of small capacity, so small as to interfere with no other enterprise or translating device except others of like character; but its diffusion is of precisely the same character as that of the rail current. Could the telephone current be limited in its path, and the claim of the telephone company be narrowed down to a specific section of earth, then, possibly, there might be some basis for the claim to the use of that section, but such a restriction is, of course, manifestly impossible. Hence, any claim the telephone interest makes to the earth must be vague; it must be all-reaching; it must be exclusive. It would seem that it has no more legal right to make a claim which prohibits a railway in the town in which the telephone circuits are operated from using the earth, than it has to make a claim that a railway in any other city with which the telephone may be remotely connected shall be prohibited likewise from using the earth in that particular city, although it may be a hundred miles off. It is a well-known fact among electricians, and probably no better known than among the telephone people themselves, that, perfectly independent of railway enterprises, a far better service can be rendered the patrons of the telephone where a complete metallic circuit is used and the use of the earth abolished. The telephone is the most jealous detecter possible of all disturbances of electrical condition on the circuit which includes it. Its very function as a transmitter of speech depends upon this marvellous delicacy. As now operated in the majority of telephone exchanges, it is subject to continual interference, not only from the railway circuit, but from every electric light, power, or telegraph with which it is brought into proximity. It is subject to interference from atmospheric changes and discharges. The telephone circuits themselves interfere with each other. Cross-talk and false signalling are common. Almost all these troubles can be avoided, and the telephone service made far more perfect, by using either the individual metallic return with the switch-board properly constructed for it, or the individual return, the return wires coming to a common terminus, which would make absolutely no change in the telephonic switch-board; or what has become known as the M'Cluer device, the use of an artificial metallic ground or common metallic return—that is, by breaking the ground connections of the individual telephones and connecting them all to one common copper return of a resistance which shall be low compared with the resistance of the instruments themselves. The lower the resistance of this common return the less any interference of the telephones with each other. The cost of this latter method is a bagatelle. It should be put up by the telephone companies for the sake of their patrons, independent of whatever other electrical enterprise they may be brought in contact with. Wherever intelligently put up the relief from outside interference has been almost absolute, and the testimony of parties who made complaint when telephone companies first sought to obtain an injunction against the railways is now emphatic to the relief which has been obtained by this change in the method of running the telephone circuits. It is unquestionable that the telephone company is waging the warfare from the standpoint of economy, pleading the rights of vested interest. Notwithstanding, every telephone expert knows the great advantage to be gained from a metallic circuit, and sundry Papers read at Telephone Conventions not only admit that the metallic circuit is best, but give testimony from the exchange superintendents that, wherever their patrons once use the metallic circuit and long-distance telephone, they are never satisfied thereafter to use the grounded circuit. It is likewise suggested that the Bell Telephone Company to-day advertise no less than about 150 local stations in New York City equipped with the long-distance telephone and the metallic circuit. Since there is not an electric railway in the City of New York, their action in this locality could not have been dictated by interference from that interest.

Since both the telephone and the railway companies occupy public streets by public licence, it is, of course, necessary to examine into the source of their respective titles, and the character of their occupancy, because otherwise it would be impossible to understand what are their respective rights. The electric railway has proved a great advance upon any method of street car propulsion hitherto known. The single trolley system being used by nine-tenths of the street railways in the United States using electric motor power, as against all other methods, certainly shows that practical experience is in favour of that particular method. As an improvement upon the method of propulsion, it would seem that an electric street railway uses a public highway, occupies the same, and enjoys the right of travel thereon as of equal dignity with any or all other persons or vehicles upon that highway, and that this right of enjoyment is within the original purpose for which the highways were opened. On the other hand, it is pertinent to inquire what right or title a telephone company has in the street. By virtue of the original dedication of the highway they have no rights except that of toleration. Telephone and telegraphs are identical in contemplation of law, and have been held to be an additional burden upon highways. In almost every case where this question has come up in the matter of telegraphs, such has been the decision. The statutes under which telephone or telegraph lines are permitted to be erected in highways provide that while they may be so erected, the poles and wires shall not interfere with public travel upon the highways. Since this is true the telephone companies are upon a public road not by virtue of right, but of toleration; not as the equals of the street railway, but subordinate to it. They occupy a secondary position, and, this being the case, where conflict arises between the two, it would seem that the telephone company must eventually yield; for its claim against any competitive enterprise is nothing less than a claim to the exclusive right of the earth. Certainly, no statute gives an exclusive privilege to a telegraph or a telephone company; and any claim for such an exclusive right, to be substantiated, must show an express or implied grant from some source, and the boundary as well as the source of that title. Not only this, but it must show that the title is exclusive. In view of the fact that the telegraph companies had used ground circuits for 30 years or more before the telephone was discovered, and that patents were refused for such use, it will be somewhat difficult for the telephone company to show the source of its title, and it is manifestly impossible to show the limits of the territory from which any other enterprise must be excluded so that it will in no way interfere with the operation of the telephone system; for the telephone circuits being attached to gas and water systems of the community in which it is located, the ramifications of such systems and of all the subterranean electric conductors of the earth in contact with these metallic conductors are unknown to science. How other electric currents entering the earth may do so without invading the charmed area of the telephone and disturbing its grounded wires no man can say, much less can the telephone people themselves. The boundaries, then, of their claim being so vague, it would seem that their claim itself must necessarily fail.

Within the past two years there have been, I believe, eight attempts made by the telephone interests to get an injunction. The first was in Akron, Ohio, in the latter part of 1888, where the Central Union Telephone Company of Chicago attempted to restrain one of the Sprague roads by injunction. This was denied. The next suit was against the Harrisburg road and the Sprague Company by the Penn Telephone Company. The case was abandoned and compromised for the very sensible reason that it would cost less on both sides to compromise than to carry the case to the higher courts. The next attempt on the part of the telephone interests was in the application for an injunction against one of our roads at Chattanooga, Tenn. This injunction was denied. Then came a conflict in Salt Lake City, where many of the people were so interested that they said, as between the telephone and electric railway interests, if the decision was against the railway company they would abolish the use of the telephone. Such heroic measures apparently were unnecessary, for the injunction was twice denied. Then application for an injunction was made in Cincinnati, and this will probably become a *cause célèbre*; for an injunction, on what ground I do not yet know, was granted, and the case will be carried to the higher courts. In Eau Claire, Wis., an attack was made on the railway interests under cover of a State law which the telephone companies had quietly got passed, requiring a return insulated conductor for any circuit carrying electric energy. The injunction was there denied, for the telephone company had somewhat overstepped itself, and found itself quite as much in the mud as the railway company might be in the mire, so far as the law was concerned, because they were themselves the carriers of electric energy and were

Digitized by Google

using grounded circuits, and consequently had no standing before the court. The last case with which we have been directly concerned is one at St. Joseph, which has not yet been tried. In Albany, where another electric railway company is operating, the telephone interest has succeeded in getting a temporary injunction. With the records thus given, it would seem that the electric railway companies have little to fear from the attacks made upon them by the Bell Telephone Company. A just compromise, but no surrender, should be the motto of the railway company.

I have been frequently asked whether, in my opinion, electricity will ever be used on trunk lines for through passenger or freight traffic? My answer is, probably not, according to the present notion of trunk line transportation, and not by present methods of train despatching. But with these qualifications I admit my hope and expectation of rapid through transit under certain conditions. Let us for a moment consider a few facts. Railroad managers are constantly meeting with a demand for more rapid and luxurious methods of transit. I think I can safely say that as steam railways are operated, a maximum speed of 90 miles per hour, and a running speed of 60 to 70, is all that can be hoped for in steam railway travel under the best conditions which can be provided. The limitations are too many. With respect to the electric motors, the question is not now, can a motor of sufficient capacity be built, or efficiently and positively controlled, but, rather, how can the electricity be produced and supplied to the motor and at what potential can we work. We all hope to see the time when electricity can be produced economically from coal without the intervention of engines or dynamos; and it may be that something akin to the present steam practice will be common; but I think that even then it will be quite likely that a central station method of distribution will be the more advantageous. On the other hand, there are those who hope to see the storage battery so reduced in weight and improved in other particulars as to warrant its use in a large way in locomotives. For myself, I prefer to consider the possibilities of another method—the amplification and development to its full capacity of present street railway practice; and for that purpose I will briefly consider a supposititious case, namely, an express between New York, or rather Jersey City, and Philadelphia. But before considering this problem let me point out a feature or two about steam roads. When first laid through a new country they usually consist of a single track, which must do the manifold duty of providing for through and local freights, and local and express passenger traffic in both directions. The route of such a road is determined mainly with the idea of getting from one place to another by a more or less direct line, but especially by one which shall not require too costly construction. The demands of traffic make a double track necessary, and as civilisation grows apace the freight traffic demands a track by itself, and four tracks constitute the equipment. So, following the development of the road, we will find that in time the express and local passenger trains may require individual tracks, and a six-track road will be a necessity. But it must be borne in mind that the express is not intended to cater to local travel. The highest demands of such a service would require that, independently of the local travel, a through express track should be constructed by the most direct route possible between the principal localities, and every effort made to reduce the curvature and grades as much as possible. No matter how much it costs to build such a road, when the traffic is sufficiently large it will pay to do it.

Suppose such a road to be an electrical one, and the method of supply to be from one or more central stations, the current being taken by a universally flexible underneath contact from a rod carried above the car, and the return circuit made by means of the rails. What the structure of the roadbed would be need not here concern us. We might use the standard T rail and roadbed, avoiding as much as possible curves, grades and grade crossings, and the overhead rod can be used simply for supplying the current; or some form of a double or single track road slightly raised above the ordinary level, and with the upper rod forming a steadying and centreing cord as well as a current supplier may be used. These are mechanical questions with which we need not concern ourselves at present. What does concern us, however, as electrical engineers is, whether the cost of copper, the potential required, the losses on the line, and the number of stations, are such as would be prohibitory. As regards the potential, other things being satisfactory, whatever pressure is demanded in the interest of economical and effective service will be used, and means will be found, consisting mainly in cars of construction, which will make its use for the purposes, and as intended, safe and proper.

From 8 a.m. to 9 p.m., a period of 13 hours, 21 regular trains leave the Jersey City station of the Pennsylvania road to run through to Philadelphia; 12 of these make but one or two stops. In addition to these there are a number of local trains serving way stations. Taking the through trains only, and allowing an average of say five cars to a train, there are in the 13 hours about 105 through cars despatched from Jersey City, or at the rate of one car every 7½ minutes, and of the through trains not making over one or two stops there would be one every 13 minutes. We will suppose an additional express track has been built, leaving the distance about what it is now, say 90 miles, but that the grades have been eased and the worst curves rectified. For the practical purposes of this Paper I will consider that the road is level, that the cars are to be despatched in 2-car units on a perfect block system, and to run through to Philadelphia with not more than one stop, at fixed intervals, and at a high average rate of speed, say 60 miles per hour. In the systems that I would propose, practically that with which I experimented some years ago, slight grades would make little difference in the general result, especially if the grade percentage, if expressed as a whole number, did not exceed the quotient of the traction in pounds per ton divided by 20, because when $C = \frac{t}{20}$, where t = traction in pounds per net ton and C = grade percentage expressed as a whole number, the work of traction and of lifting are equal. For example, suppose $t = 10$ pounds and $C = \frac{1}{2}$ per cent., and that we had on a double track one unit coming down the grade and the other ascending it, both at the same speed: then gravity would be supplying just enough power to propel the car on the down grade at a fixed speed, and enough power to supply the lifting and traction work of the other car would have to be supplied, which would be just the amount required to propel both cars on a dead level. Suppose the grade to exceed the ratio expressed above, then the car on the down grade would have an excess of falling energy, and this could be used in accelerating the speed of the car, or on the brakes, or it could be used by a process of reconversion for the purpose of supplying at short range part of the extra energy required by the ascending train. Just how this can be done is pretty fairly understood by electricians. All motors starting running on a level, or ascending a grade, would be requiring currents. All motors running on a down grade with just that velocity which the force of gravity would give them would require no current; and motors running on down grades of greater percentage than is required to give them power for traction, or motors slowing down, would be generating currents to aid in the general supply. No other system of distribution can by any possibility have this very remarkable interchange of energy. When running at a particular speed a slight movement of a regulating handle would make the motor receive from or give to the line currents in any desired quantity. The braking power of a motor thus acting as a generator is very powerful and the most perfect imaginable; because, unlike the ordinary methods, the brake does not operate if the wheels stand still, the very essential of the braking operation requiring the wheels to turn. It is a well-known fact that the most effective brake-work is when the wheels do not skid upon the track, but when they are turning under the pressure of the brake; and, contrary to the ordinary braking practice, the energy of the electric train, instead of being thrown away in the form of heat and using up our wheels and brake-shoes, can be made useful in the propulsion of other trains. I have tried this method of braking with such a degree of refinement that a heavily-loaded car would creep on a down grade at a pace so slow that an egg could be put under the wheels and cracked and removed before the wheel would pass over it.

Having thus touched upon the characteristics such as I would propose for a railway system of this kind, let us resume the consideration of our proposed line between New York and Philadelphia, and try to form some idea of the electrical pressure which would be required, the service which could be demanded, the number of cars which could be handled, the speeds which could be maintained, and the number of stations which would be required to operate the stations. We will assume for the purpose of this investigation an overhead conductor in the form of a solid rod one inch in diameter over each track, or, if you please, a smaller rod over each track, and a main conductor making up the equivalent capacity proposed, and a track of equivalent capacity. I take this arbitrary size because it is convenient for the purposes of our calculations, and because it falls well within the limit of expenditure which such a system would warrant. For instance, the American Bell Telephone Company has a line of long-distance telephone wires rounding from New York to Boston, a distance of about 300 miles, nearly three and a-half times the distance which we are considering. On these poles are about 70 wires each of No. 12 copper. The aggregate area of these conductors is over 800,000 circular miles, and the total weight of copper on this line, which is used simply for telephonic purposes, is about 40 per cent. more than the weight of two copper rods an inch in diameter running from New York to Philadelphia. If the investment is a reasonable one in the telephone system, cannot we certainly consider it a reasonable one in that larger field of the transmission of power of which we are now speaking?

As I have stated, of the number of trains which in 13 hours leave Jersey City for Philadelphia, 12 usually make only one or two stops. Allowing 60 cars, this would be about one car every 13 minutes. This interval of 13 minutes is nearly as short as would be desirable between cars running at an average speed of a mile a minute, no matter how perfect the block system, and it would be necessary, possibly, to run these cars in double-car units.

Digitized by Google

We will assume for our purpose the size of a car such as is used on the elevated road of Brooklyn bridge in New York, which would with motor and passengers weigh from 20 to 25 tons, or a total of, say, 50 tons for our unit. The formula to determine the size of conductor for a single transmission of car is

$$C M = \frac{15666\, n\, l}{e\, v\, p},$$

where n = the number of horse-power, l the distance in feet, e the potential at the motor, v the fall in potential, and p the commercial efficiency of the motor. If we assume the station situated in the middle of the line—that is, at the best point—and the work divided equally at the middle section on each side, then, l being the length of line, we have the formula

$$C M = \frac{15666\, n\, l}{4\, e\, v\, p}.$$

This will be practically the same if the work is distributed over the entire line.

If more than one station is used, then the formula will become

$$C M = \frac{15666\, n\, l}{4\, e\, v\, p\, s^2};$$

that is, the size of the conductor would vary inversely as the square of the number of stations (s), if properly distributed. v may be expressed as a fraction of e, and, for practical purposes, we will let $v = \frac{1}{9}$th of e and p, such that

$$\frac{15666}{p} = 16800;$$

that is, p = about 93 per cent. Then we have

$$C M = \frac{37800\, n\, l}{e^2\, s^2},$$

which may be expressed thus: that the size of the wire varies inversely as the square of the product of the number of stations and the electromotive force.

We may also note that with any fixed size of conductor the electromotive force and the number of stations vary inversely, a somewhat important fact to remember.

We have another formula, one for the power required by a moving car, which is

$$\text{horse-power} = \frac{4}{75}\, w\, m \left(c + \frac{t}{20} \right),$$

where w = the weight in net tons, m = the miles per hour, c the percentage of grade expressed as a whole number, and t the traction in pounds per net ton.

As I have stated, we will assume in this formula that c equals zero, a consideration in which I am justified in express service on a road of the character I have outlined, with the relation of grades and traction given, and with the method of braking I have described. Our formula would then become, using 10lb. per ton as our average traction,

$$\text{horse-power} = \frac{2}{75}\, w\, m,$$

which, substituted for n in the distribution formula, gives us

$$C M = \frac{1008\, w\, m\, l}{e^2\, s^2};$$

or, substituting for l 5280 d, d being the number of miles between stations,

$$C M = \frac{5322240\, w\, m\, d}{e^2\, s^2}.$$

We have assumed for our conductors two rods an inch in diameter, and that the rail has the same resistance. Hence, substituting for C M its value 2,000,000, we have

$$e^2 = \frac{2{\cdot}66112\, w\, m\, d}{s^2},$$

or

$$e = \frac{1{\cdot}631}{s} \sqrt{w\, m\, d}.$$

It will be noted that m, w, and d—that is, number of miles per hour, weight-handled, and distance over which operated, are all affected in the same way. Hence, with any value of e and s we can vary the relative values of w, m, and d so long as we do not disturb the product. That is, we can halve the number of miles and double the speed, or double the distance and halve the running speed, keeping the weight hauled the same, and so on. For the total weight we can substitute the weight of each unit, c, and the number of units, b, thus making the formula

$$e = \frac{1{\cdot}631}{s} \sqrt{m\, b\, c\, d}.$$

For the line proposed $d = 90$, and we have

$$e = \frac{15{\cdot}56}{s} \sqrt{m\, b\, c}.$$

Taking our unit of two cars at 50 tons, the time intervals between them as ten minutes, and 60 miles per hour as the mean speed, we have on the whole system 18 active units of two cars each, and

$$m\, b\, c = 54000$$

which substituted in our formula is

$$e = \frac{3616}{s}$$

which means that with one station in the middle, the potential at the motor farther from the station would be 3616 volts, and near the station one-ninth higher. Can we handle it? Yes, in time; but, perhaps, not yet. Nor is there any necessity for doing so; for if we increase the number of stations and go to a 3-wire, instead of a 2-wire system, making the track the balance circuit, we would have motor potential as expressed by the following table:—

Stations.		Motor Potential.	
Number.	Miles apart.	2 Wire.	3 Wire.
1	—	3616	1808
2	45	1808	904
3	30	1205	603
4	22½	904	452

Which last brings us down to ordinary street-car practice, which is only the beginning of what will be done in the effective handling of potentials. So, after all it does not seem such a serious electrical problem, and certainly not one to shrink from. We can in another way illustrate the influence of the position and number of stations and the potential used. Suppose we had a station at Jersey City to supply the entire line as a certain potential over a conductor of the required size. If the station be moved to the centre, the weight of copper necessary is only one-quarter. Use two stations properly spaced and the weight is quartered again. Double the potential and the weight is further quartered. Now use the 3-wire system and the weight is again quartered. So that by these very simple processes the original weight has been reduced 1-256th of the original.

I do not think I need to point out further the value of a proper determination of electrical values in a problem of this character. We see, then, that the suppositious case is well within the range of possibilities. A 60-mile express service every ten minutes instead of 40 to a 45 mile service every hour, would revolutionise travel. Of the comforts of such a mode of travel, I need not speak. That it will in the not very distant future be a fact, I know you all agree with me in hoping for.

MEETINGS OF SCIENTIFIC SOCIETIES, &c.

(To-night) FRIDAY, March 7th.

PHYSICAL SOCIETY.

5 p.m. Ordinary Meeting. Papers to be read: "Bertrand's Refractometer." By Prof. SILVANUS THOMPSON, D.Sc. "An Apparatus for Distillation of Mercury in a Vacuum." By Prof. DUNSTAN and W. DYMOND.

ROYAL INSTITUTION.

9 p.m. Evening Discourse: "Electrical Relations of the Brain and Spinal Cord." By FRANCIS GOTCH, B.Sc.

SATURDAY, March 8th.

ROYAL INSTITUTION.

3 p.m. Afternoon Lecture: "Electricity and Magnetism." By the Right Hon. Lord RAYLEIGH, F.R.S.

SOCIETY OF ARTS.

3 p.m. Popular Lecture I.: "The Atmosphere." By Prof. VIVIAN LEWES.

TUESDAY, March 11th.

INSTITUTION OF CIVIL ENGINEERS.

8 p.m. Ordinary Meeting. Papers to be discussed: "The Hawkesbury Bridge, New South Wales." By C. O. BURGE, M.Inst.C.E. "The Construction of the Dufferin Bridge over the Ganges at Benares." By F. T. G. WALTON, C.I.E., M.Inst.C.E. "The New Blackfriars Bridge on the London, Chatham, and Dover Railway." By G. E. W. CRUTTWELL, M.Inst.C.E.

WEDNESDAY, March 12th.

SOCIETY OF ARTS.

8 p.m. Ordinary Meeting. "The Chemin de Fer Glissant, or Sliding Railway." By Sir DOUGLAS GALTON, F.R.S.

THURSDAY, March 13th.

INSTITUTION OF ELECTRICAL ENGINEERS.

8 p.m. Ordinary General Meeting. Adjourned Discussion on the following Papers:—"The Theory of Armature Reactions in Dynamos and Motors," by JAMES SWINBURNE; and "Some Points in Dynamo and Motor Design," by W. B. ESSON.

The Electrician.

Published every Friday. Price Fourpence; Post Free, Fourpence Halfpenny.
Editorial, Publishing and Printing Offices:

SALISBURY COURT, FLEET ST., LONDON, E.C.

Telephone No. 2714. Telegrams: "ELECTRICIAN NEWSPAPER, LONDON."

All Communications to be addressed to "THE ELECTRICIAN," *Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to* "THE ELECTRICIAN."

All letters intended for insertion in "THE ELECTRICIAN," *or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

"THE ELECTRICIAN" *is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.*

"THE ELECTRICIAN" *is on sale at the railway bookstalls throughout the United Kingdom on Friday morning, and can be obtained of all Booksellers and Newsvendors; or direct from the Publishing Offices as above.*

SPECIAL NOTICE.

Owing to the increase in the number of pages of "THE ELECTRICIAN," in order to partly cover the increased postage, we have been compelled to revise the rates for Foreign Subscriptions, which are now as follows:—

	3 months.	6 months.	12 months
For Foreign Parts and Colonies:—	s. d.	s. d.	s. d.
Within Postal Union	6 6	12 6	24 0
Aden, Borneo, Ceylon, China, India, Japan, Java Labuan Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7 6	14 6	28 0
The rates for the United Kingdom remain as follows:—	5 0	10 0	19 6

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to the office.

TRADE ADVERTISEMENTS *intended for the current issue must be handed in not later than First Post on Thursday morning.*

SMALL PREPAID ADVERTISEMENTS *(for Rates see page xv.) are accepted up to 4:30 p.m. on Thursday.*

TECHNICAL PRINTING.

"THE ELECTRICIAN" PRINTING AND PUBLISHING COMPANY (LIMITED) *beg to inform Electricians, Electric Light Engineers, &c., that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

"THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK.

Royal 8vo, 5s., postage extra.

Early in each year is issued "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1889 Edition consisted of more than 600 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with popularly-written Biographical Notices of the leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

The issue for 1890, which is still further enlarged and improved (making 850 pages), is NOW READY. Orders should be forwarded at once to the Publishing Offices, Salisbury-court, Fleet-street, London, E.C.

SEEING BY ELECTRICITY.

Shall we ever see by electricity? If a cable or a mere line of wire is capable of conveying, not merely signals, but sounds, music, and even speech, by means of electric impulses transmitted through it to a far distant spot, why should not the same medium of communication, actuated by the same subtle agent, be used to convey to us pictures of men and things? This question was frequently asked a dozen years ago when electric telephoning was a comparative novelty. The world awoke to the fact that it could hear through an electric wire, and forthwith it demanded that through an electric wire it should also be allowed to see. That no practical means have yet been discovered to solve the problem of seeing by electricity is not the fault of the inventor; for many inventors, even amongst the ablest and most successful, have attempted its solution. Neither is it the fault of the capitalist; for, assuredly, plenty of money can be found when needed to exploit so splendid an invention, if once the invention is made. Yet the world still waits expectant, and the invention seems no nearer than it was ten years ago.

To the casual observer, uninitiated in the secrets of physics, it is perplexing that any such delay or difficulty should arise in the designing of an instrument of such obvious value. It is an everyday fact that electricity can bring light into our

Digitized by Google

houses, can illuminate them with a brilliancy unrivalled by any other artificial means. If, then, electricity can convey electric light, and can also enable us to convey speech, why should it not also enable us to convey sight? The answer to this presentation of the problem is, that the physical basis of vision is in reality much more complex than the physical basis of audition; and that though an electrical mechanism can be contrived of quite a simple character which will virtually listen to a sound at one end of a line and repeat it audibly at the other end, it is in the very nature of things that no simple electrical mechanism is possible—at least, by the light of present knowledge—which will view an object at one end of a line and reproduce an image of that object visibly at the other end. Consider how essentially different is the physical structure of the ear from that of the eye. A drum-skin which can be pushed inwards or drawn slightly outwards by the impact of the sonorous impulses transmits the motion of its middle-point through a chain of little bones to the interior nervous apparatus. The impulses come one after the other successively in time, and all that the hearing mechanism has to do is to receive these impulses, large or small, brief or dilatory, and transmit them one after the other to the nerve structure. Speech, song, music—noise, indeed, of any kind—is made up of a succession of impulses. All that a mechanical chain of bones is required to transmit from the outer to the inner structures of the ear can equally certainly be transmitted along an electric wire. There is no crossing of impulses, no focussing, no question of impact on specific portions of the tympanic surface, merely succession in time, all impulses travelling at the same rate in the one case mechanically along the chain of little bones in the ear, or in the other case electrically along the wire.

In the eye, however, the physical mechanism is of quite a different order. A beautiful combination of lenses, one of them liquid, with two others of a gelatinous nature behind them, actually focuses the light-waves upon a sensitive surface, which is differentiated into hundreds of thousands of separate structures, each one of which is capable at the same time of receiving a distinct impression. When a complex object, such as a landscape, the page of a book, or a human face, is viewed by the eye, wavelets of light emitted or reflected from each minutest part of that object enter the eye, cross one another, and focus themselves on the structures of the retina, forming there an "image" inverted top for bottom, and "perverted" right for left. The minute structures of the retina, the so-called "rods and cones," feel simultaneously all the details of this inverted and perverted picture, and in turn transmit to the sentient brain the impulse caused by the breaking of the wavelets on each of them. These rods and cones are packed together, about twenty-five million of them to the square centimetre, or about at the rate of one hundred and sixty million of them to the square inch. Suppose a page of printed paper ten inches square is placed in front of the eye, at an easy distance for vision: its image on the retina of the eye will about cover one single square centimetre, or a space in which there are over twenty millions of separate sensitive structures, each one of which can, simultaneously with all its fellows, feel that detail of the page the image of which falls upon it. A human face five feet away will similarly form an image, covering perhaps a million separate sensitive points. These points feel the details of the image, and if the face is known to the beholder, a single instant suffices for recognition. A flash of lightning, lasting perhaps the hundred-thousandth of a second, suffices to reveal a landscape or a score of faces, the eye being able to grasp simultaneous impulses coming, in the form of waves of light, simultaneously, in a number of different directions at once.

Now, consider what sort of an electric mechanism could possibly act as a far-seeing eye, in the same sense as a telephone acts as a far-hearing ear. The transmitting part must resemble the retina of the eye in being differentiated into a vast group of minute independent structures, sensitive electrically to light. Theoretically these could be constructed out of selenium cells, selenium being, as every electrician knows, sensitive to light. Imagine, then, a set of selenium cells, a million in number, arranged like the squares of a chess-board, or like the cells of a honey-comb, side by side—if each is only of the size of one square millimetre this electric retina will occupy a square metre of space; in front of this, a combination of lenses to form an image, which combination could not well have a less focal length than one and a half metres. 'Tis a gigantic electric eye. But the transmitter is only half the apparatus. At the other end must be a receiving apparatus to reproduce the image. This must be a similar sort of chess-board or honey-comb, the cells being, however, composed not of something which is electrically sensitive to light, but of something which is optically sensitive to electric currents. Each cell must, in fact, emit light when an electric current passes through it. It is possible to conceive of some as yet uninvented glow lamp of extraordinary delicacy that may serve the purpose. Or each cell may consist of a mechanism that uses secondary light; an electro-magnetic apparatus that withdraws a shutter from a minute illuminated pane, or turns a mirror to a proper reflecting angle, being within such a category. Each minute cell in such a receiver must then be connected up by a special line to its own corresponding cell in the transmitter. Such an array of lines from cell to cell is appalling to imagine. Given, however, the apparatus we have thus schemed out, it is easy to see that whenever any object is placed within the field of view of the transmitter, an image of it, not in colours but in a mere monotone of tint, will be reproduced by the receiver at the distant station. The conditions are, however, so improbable, the arrangements so complex, that the problem of constructing a practical far-seeing instrument on these lines is not likely to come to any practical solution. Perhaps one day some sort of electro-optic action may be discovered, entirely different from that which light exercises on selenium, which may place the problem on a wholly different and simpler basis.

At present the main difficulty lies not so much in the design of transmitting or receiving organs as in the necessary complexity of an apparatus which shall enable innumerable points in the transmitting and receiving retinas to be actuated simultaneously in perfect independence but also in perfect correspondence. If it were not desired to obtain actual views—if, in fact, simultaneity of action were not insisted on—then one line wire, successively connected to the separate corresponding points of the picture at the transmitting and receiving ends by some appropriate synchronising mechanism, might be made to do duty for a large number of cells, instead of employing a separate line for each. But this is not seeing by electricity; it is merely reproducing a pattern or print automatically, point by point, by electricity. And, indeed, this was done nigh ten years ago by Mr. Shelford Bidwell, when he devised his telephotographic apparatus. Since that time the subject of electric transmission of pictures has not advanced a single step. We do not, of course, forget that it is now proven that light is itself an electric phenomenon—that waves of light are, in fact, electric waves—and that all seeing is really seeing by electricity. But, since it is a fundamental point in the modern science of electricity that all conductors so-called are necessarily opaque to electric radiation, the recognition that light-waves are electric waves adds nothing to the possibility of seeing through an electric wire.

Digitized by Google

It has not yet been shown that a vibration having a periodicity of 20,000 per second can be transmitted through an electric wire, whether of iron or copper, of even so moderate a length as ten miles. The periodicity of the slowest light-waves (those that are at the red end of the spectrum) is about 400 millions of millions per second. It may be doubted whether alternate currents of such high periodicity can penetrate through a copper wire an inch long. Hence the direct transmission of electric waves that should correspond to the impinging light-waves, in the same manner as the electric currents in a telephone correspond to the impinging sound-waves, is quite out of the question. There is more hope of seeing through the proverbial brick wall than of seeing through a copper wire. Such a conclusion may seem very unsatisfactory: it may damp many eager hopes. Nevertheless, there is no other conclusion possible in the present state of electrical science.

THE INSTITUTION OF ELECTRICAL ENGINEERS.

SOME POINTS IN DYNAMO AND MOTOR DESIGN.*

BY W. B. ESSON, MEMBER.

(Continued from page 426.)

4. RATIO OF ARMATURE SECTION TO FIELD-MAGNET SECTION.

In the early days of dynamo-designing the cross-section of the armature core in cylinder machines was very small in proportion to that of the field magnets, the copper in the armature was excessive, and the air gap correspondingly great. The result was an induction no greater than in modern machines, but an enormous stray field. In the machines made by my firm six years ago, the section of the armature core was about one-third of the section of the magnets, the latter being of wrought iron. I may say these machines anticipated Mr. Swinburne's latest notions, inasmuch as the 14in. armatures of those days were loaded to 25,000 ampere-turns. The first great improvement consisted in doubling the iron and halving the copper, a machine so modified giving about the same output, but with less heating and less sparking, and requiring less magnetising force. We got the same output for two reasons: first, the decreased magnetic resistance resulted in an increased total induction; secondly, of this induction a far higher proportion was utilised. The ratio of the armature section to the magnet section, when modified as above, stood at ·66; but we went much beyond this in increasing the iron in the armature, finding that we obtained for every increase, keeping the air gap the same, an increase in the induction. The latter was not, of course, in proportion, but it was still very considerable, as will be realised from the fact that in an armature having a ratio of ·75 the induction was 10 per cent. greater than in one having ·6. When Mr. Kapp read his Paper here on "Characteristics,"† I mentioned that then the ratio in our dynamos stood at ·75. Since then we have, in machines for incandescent lighting, returned to ·6, for a reason which will be by-and-by apparent. It may be mentioned here that when the magnets are of cast iron the ratio is ·33, while the cast-iron yokes for wrought-iron magnets are from two to two and a-half times the area of the wrought iron.

I bring this forward because it is of some importance when the aim is to construct dynamos having a large output for their weight. The weight of the armature is only a fraction of the total weight of the machine. The field magnets are many times heavier, but, beside these, the bed-plate, bearings, &c., make up a large portion of the weight; and since the weight of neither magnets nor bed-plate is increased by an increased armature section, manifestly, if a large output for the weight is the object, and if nothing occurred to interfere with the process, the cross-section ought to be increased to such dimensions that for any further increase to the total weight of the machine we get no corresponding advantage.

Some interesting experiments to determine this point, which completely corroborate my own, were made by Mr. Dugald Jackson, of Cornell University, and communicated by him in 1887 to the American Institute of Electrical Engineers.‡ These experiments can be consulted by those interested; for the present my remarks are based on the results obtained. Assume that the iron core of a cylinder armature having a ratio of ·6 is one-tenth of the total weight of the machine: then, by increasing the ratio to ·75—that is, roughly, increasing the weight by 25 per cent.—we make an increase in the total weight of 2·5 per cent. But the increase in the induction will be about 10 per cent., so that clearly an advantage has been gained by increasing the section. If we increase the mass of the armature core by 50 per cent., it makes 5 per cent. increase in the total weight, but we get 15 per cent. increase in the induction. If we go farther we shall still get an increase, but it gets correspondingly less with each addition to the weight. The actual increase may not be in all cases in the proportion I have given. Necessarily it depends upon the design of the machine, but in the particular dynamo to which my remarks refer the results were as stated; and what I wish to point out is that in light-weight dynamos the armature must have a comparatively large section, and be worked at a lower saturation. Though the output for the armature weight is less, the output for the total weight is greater.

There is a limit to increasing the cross section of the armature, which is reached when self-induction troubles us by creating a tendency to sparking, and cross induction troubles us from the diminished saturation of the core. Accordingly the practical limit in this direction is fixed for us at about ·75, and the induction at 14,500 or 15,000 C.-G.-S. per square centimetre. It must not be forgotten that increasing the section of the core increases the length of the wire on it by a small percentage.

Pressing the induction up to high values is not advisable, as the magnetism then costs too much. It will be seen from the curve (Fig. 1) that the magnetising force to produce an induction of 18,000 per square centimetre is about twice, while the magnetising force for 20,000 is more than six times, that required for 17,000.

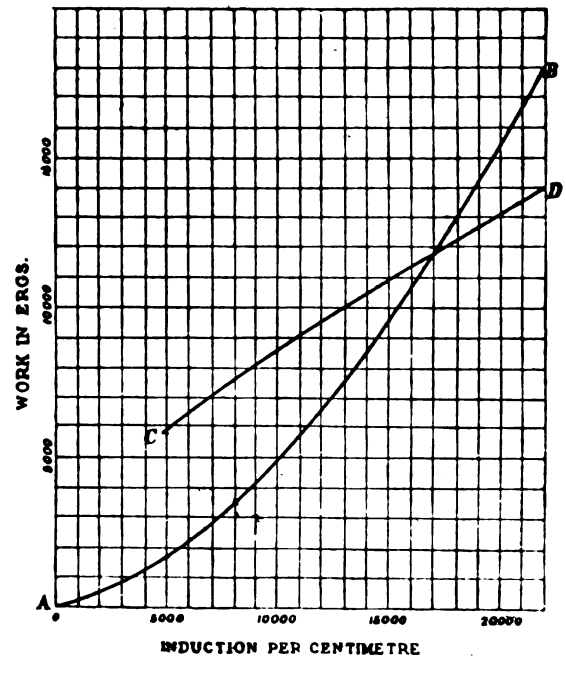

FIG. 14.

As the core saturation is increased the stray field is increased, while the heating due to hysteresis is also greater. Everything considered, 17,000 per square centimetre is probably the best degree of saturation to employ for cylinder armatures, and makers who once employed a greater induction are, I believe, coming down to this. If we work lower we get on the bend of the curve, or on that part where the angle changes rapidly; so that it is not possible to obtain in compound machines with a lower induction such perfect regulation. It may be mentioned in passing that, since the loss of potential in the armature and series winding is generally in slow-speed machines a higher proportion of the E.M.F., in these the difference in the induction on open circuit and at full load is proportionally greater, and the compounding, in consequence, less perfect.

There is no particular advantage in reducing the induction, save that of obtaining a higher weight efficiency. The reduction of the loss due to hysteresis is very small, and less than might at first sight be imagined. In Fig. 14 is given a curve, A B, showing the energy in ergs required to carry a cubic centimetre of iron through a complete cycle of magnetisation at different degrees of saturation. Induction per square centimetre is measured by abscisse, and the energy by ordinates. It will be observed that for 17,000 the energy is greater by about 24 per cent. than for 15,000; but for an armature of given output the cross-section of the core has to be increased in proportion as the induction is diminished, and the total work expended in carrying the armature through a cycle of

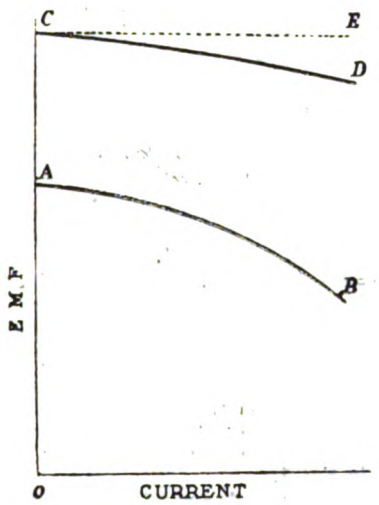
Digitized by Google

magnetisation is, roughly, proportional to the ordinates of the curve C D. To draw this curve an induction of 17,000 is taken as the normal, and all the ordinates of A B multiplied by the ratio of 17,000 to the induction. It will be observed that for any specified output there is only about 8 per cent. more power wasted in hysteresis at an induction of 17,000 than at 15,000.

In four-pole machines it is usual to saturate the armature to a lower degree—about 14,000; and in alternators the induction is still less—about 6,000. As the curve A B gives energy in ergs, the watts expended in the armature are found by multiplying this by the number of cycles per second and by the number of cubic centimetres in the armature, and dividing the product by 10^7. In drum machines the induction per square centimetre is rather over half of the value given for cylinders, and the ratio of armature to field section varies from ·8 to 1·0. The diameter of the armature being fixed with reference to the number and size of conductors, there is nothing to be gained by cutting away the interior of the washers. On the contrary, by cutting an opening only large enough for the shaft, the induction is kept low, and the magnetising force for the armature correspondingly small, while the heat generated due to hysteresis is also diminished.

5. Interference of the Armature Field.

Though iron may vary in quality, and so upset occasionally our calculations, no great difficulty need be experienced in approximating pretty closely the magnetising force required for a given induction in the armature core. But when we allow a current to flow in the coils, and so magnetise the core, we superpose on the original a second field and the interference between them renders the case no longer simple. If we excite the field magnets of a dynamo with a constant current, and allow currents of various magnitudes to flow



C. D. Strong Field.
A. B. Weak Field

Fig. 15.

through the armature, we find on maintaining the speed uniform that the E.M.F. falls as the current is increased. In 1884* some investigations of mine were published which dealt with this question, and established the result that when the ampere-turns on the armature were few, and the field strong, the fall of E.M.F. with a fixed load was about proportional to the current. As the field was weakened the line representing the E.M.F. began to bend, until, when it was very weak, a kind of inverse characteristic was obtained, as shown in Fig. 15. In fact, the results are similar to those which would be obtained by reducing the winding on the magnets; the effect due to this being small when the magnets are fairly saturated, and large when they are far from saturation. It was then observed that the Hefner von Alteneck winding produced least weakening effect on the field, while the now defunct Bürgin produced most, the Gramme taking a position between these two. Since that date electricians have talked frequently of the weakening effect on the magnets of the current flowing in the armature; but though it is admitted that the induction is the resultant of the magnetising forces both on magnets and armature, the conditions determining this resultant are by no means clearly comprehended.

Consider the magnetic system shown in Fig. 16. N and S are the North and South poles of a field magnet, the magnetising currents flowing into and out of the paper as shown by the open and crossed circles respectively. There is no current flowing in the armature coils, and the lines of force flow from pole to pole through the core as indicated by the dotted lines. Imagine that the current flowing round the magnet is stopped, and that a couple of brushes placed on the collector at S N (Fig. 17) cause a current to flow through the armature winding alone. We have the lines along paths indicated by the dotted lines, and obviously through this circuit at right angles to the other the cross induction depends, for a given number of ampere-turns, mainly upon the length and cross-section of the air gap. If we place the brushes at right angles to this position, we have no cross induction, but, instead, an induction taking the same path as the forward induction, though in an opposite direction. If the current is allowed to flow through field and armature coils at the same time, as it does in actual machines, we have the distribution of field as sketched in Fig. 18, the lines of force due to the magnets being pushed towards the left-hand top corner and right-hand bottom corner of the poles. Where the armature or cross-induction opposes the magnet or forward induction, the field in the air gap is weakened; where the cross

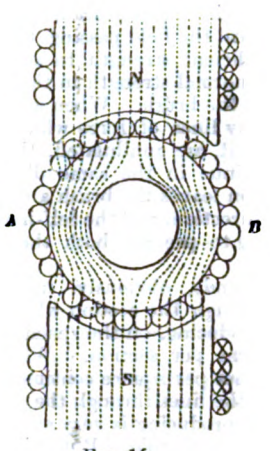


Fig. 16.

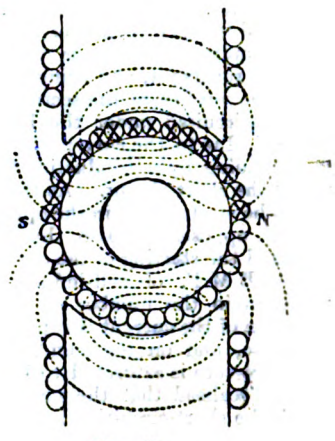

Fig. 17.

induction helps the forward induction, the field is strengthened. In consequence of this distortion with reference to the brushes, the sections under them have become active, and to avoid sparking a

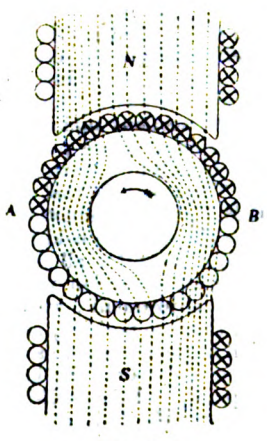

Fig. 18.

lead must be given, which will remove the commutated sections beyond the sphere of activity. This lead diminishes the forward induction, at the same time diminishing the distortion with reference to the new position of the brushes.

6. The Effect of Distortion on the E.M.F.

The distortion of the field produces in a dynamo run without lead a diminution in the E.M.F., for two reasons—first, because the induction acts differentially on the conductors lying between the brushes; secondly, because the currents flowing in sections active when short-circuited under the brushes weaken the field. These local currents induce lines in the opposite direction to the forward induction.

Let the machine run as a motor in the opposite direction, the currents flowing through the field-magnets and armature being of course in the same direction. The E.M.F. is induced in the armature in the opposite direction, and since in an active coil short-circuited under the brushes the current will flow in the direction of the induced E.M.F., its effect will be to directly strengthen the

* "The E.M.F. of Dynamo Machines Excited by a Constant Current," *Electrical Review*, Vol. XIV., p. 303. 1884.

Digitized by Google

field as it increases the forward induction. We may say, then, that the effect of distortion is to diminish the E.M.F. in a dynamo run without lead, and increase it in a motor, owing to the local currents generated in the short-circuited coils.

The difference in the E.M.F. of a machine run without lead as dynamo and motor may be considerable, as shown by Prof. Ayrton's experiments at the beginning of last year.* These experiments were made on a drum machine which had a comparatively weak field. I am not quite certain as to whether the cause here given is sufficient to account for the difference, but I believe that were the brushes adjusted in each case until the local currents were annihilated, the same E.M.F. would be, with properly laminated armatures, generated by both dynamo and motor. That there is a certain amount of power wasted in these currents is quite obvious, though from their tendency to lessen the distortion in the motor, their magnitude, and the consequent waste, is in the motor less.

7. Position of the Brushes in Dynamos and Motors.

If dynamos are to run sparklessly there must be a lead given to the brushes, or, in other words, the point of collection must be advanced in the direction of motion until the field passing through the commutated sections is just of sufficient strength to stop the current, reverse it, and bring it to its normal strength in the opposite direction before the section leaves the brush. When a section is short-circuited under the brush, any lines of force which were induced, due to the current flowing in it, are annihilated, the current tending by self-induction to continue in the same direction round the short circuit. As the section leaves the brush a current has to be started in it in the opposite direction, and the self-induced E.M.F. opposes this also, thus tending to prevent both the stopping and the starting of the current.

The E.M.F. of self-induction depends, obviously, upon the variation in the number of lines through the section which the cessation of the current is capable of producing, on the speed of the armature, and on the number of turns per section. When an armature core is saturated to 17,000 lines per square centimetre, it will be realised that the variation in the lines through the section which the short-circuiting is capable of producing is very small; in fact, we may say that it is practically negligible. But, with the smallest amount of self-induction present, it takes a certain time to effect these changes in the section, and the brush must be of such thickness that the changes are effected before the short-circuit is removed. The brush must be placed in advance of the neutral point: in an armature, for instance, having 50 sections, presuming that 5 volts are wasted in the armature, a section when it leaves the brush must move in a field having such strength as will neutralise the effect of self-induction, and give one-fifth of a volt over. If the armature has 100 sections, the field must give a resultant of one-tenth of a volt; but the E.M.F. due to self-induction will be in the latter case only one-fourth of what it was in the former. By saturating the core, and making the sections sufficiently numerous, we can make the self-induction as small as we please; and in machines in which the current varies from 0 to a maximum, we purposely make it as small as possible. The reason is, that as the current increases, the variation in the E.M.F. of self-induction does not correspond with the variation in the shape of the field for different positions of the brushes, perfect adjustment for all currents being therefore difficult. By making the self-induction very small we get a close approximation to perfect adjustment; we can place the brushes very little in advance of the zero position, reducing in this way the adjustment for variation in the current to a minimum.

We see, then, that in a dynamo the brushes must be set in advance of the neutral point, and that self-induction increases the lead. Is the trail in a motor similarly increased? The answer is that it is. The brushes must be set in a motor behind the neutral position, so that the induced E.M.F. is in the same direction as the current to be started in the section, and so that the E.M.F. of self-induction which opposes the starting is neutralised. It appears that the best position for the brushes in a motor is the position in which they have about the same trail as they have lead when the machine works as a dynamo, and that in a motor the trail is *increased* by self-induction.

(To be continued.)

International Exhibition at the Palais de l'Industrie.—The Société Nationale des Sciences et des Arts Industriels are preparing an Exhibition to be held in Paris this summer, at the Palais de l'Industrie. The Exhibition will be open from July to November; Class 20 will include batteries, dynamos, &c., and Class 21 telegraphic and telephonic apparatus.

THE ZIPERNOWSKY-DERI-BLATHY SYNCHRONOUS MOTOR.*

A synchronous motor is set in motion by an alternating current sent through the armature, and when working under normal conditions the number of revolutions is equal to the number of alternations. An alternator, the magnets of which are excited by a direct current, can be used without difficulty as a synchronous motor; but the alternator must be brought to synchronism before it will work. The magnets of a synchronous alternating motor can be excited by an alternating current; for this purpose a revolving commutator is necessary to give the requisite direction to the current impulses in the magnets. In its simplest form such a commutator consists of as many segments as the motor armature contains coils, the even segments being connected to one another and to one end of the magnet coils, whilst the odd segments are also

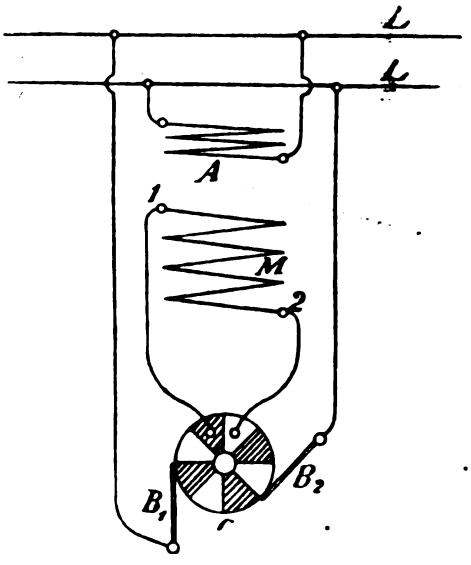

Fig. 1.

L L = Leads. A = Fixed armature. M = Maguet coils. B_1 B_2 = Brushes.

connected to each other and to the opposite end of the magnet coils. If the brushes are given the proper position it is evident that (supposing the motion to be synchronous) each time the current changes its direction the connections to the magnets will be reversed, so that the magnets are excited by a uni-directional intermittent current. A diagram of the essential parts of such a motor is shown in Fig. 1.

In a motor with fixed magnets and rotating armature two additional pairs of sliding contacts are required to supply the armature with current and to take the current off the commutator to the magnets. Motors arranged as above can also be started by an alternating

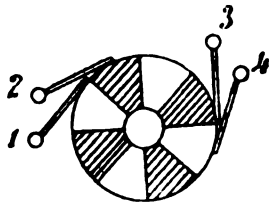

Fig. 2.

current, but the iron of the field-magnets must be protected against Foucault currents. When in such a motor a favourable position is given to the armature and the magnets (or a slight motion imparted), an alternating current will start it, and the speed will increase until it is running synchronously; but practically such a machine is useless on account of sparking, both during the first motion and at full speed.

It is this difficulty which Zipernowsky, Deri, and Blathy claim to have overcome. The sparks are caused by the extra currents induced at each alternation. The current is only strong enough during part of the period to keep the magnets sufficiently magnetised, and when the strength falls off an extra current is induced in the magnet coils. At this moment a path of low resistance is provided and then immediately broken again. Sparks are the result. The intensity of the fields also undergoing great fluctuations, the speed of the

* From the *Elektrotechnisches Echo*.

Digitized by Google

motor is very uncertain, and it easily falls out of synchronism. All this is overcome by short-circuiting the magnet coils a short time before the reversal of the current, the brushes being so arranged that at the moment of segment-change the extra current acts in opposition to the main current, getting rid of the sparks. The momentary short-circuiting is effected by employing four brushes, which are connected as shown in Fig. 2; 1 and 2 being connected with one lead, and 3 and 4 with the other, the magnet coils being short-circuited during the time that the brush 2 is on the shaded segment. The distance between the contact points of the brushes 1 and 2 is $\frac{1}{4}$ to $\frac{1}{2}$ of the width of a commutator sector. It is, of course, not necessary that the brushes at one end of the conductor should be on the same segment, as they may be on different segments of the same class, as shown in Fig. 3, the effect being the same; or, instead of two separate brushes, one with a broader bearing surface may be used. Numerous tests show that with this arrangement of short-circuiting the brushes sparking at the commutator is obviated, and the motor runs synchronously.

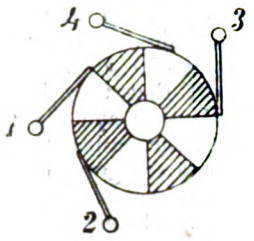

Fig. 3.

The above arrangement is perfectly satisfactory when the motor has attained the synchronous speed; but starting is difficult, and the torsional moment being small, the normal speed is not quickly reached. At starting, a slight displacement of the brushes is necessary. An arrangement has therefore been adopted by which one brush of each pair, 1 and 3 or 2 and 4, may be cut-out at starting, or both of each pair 1 and 2 and 3 and 4 are brought to the same respective segments, so that no short-circuit occurs. As soon as synchronism has been reached, the arrangement permits the other two brushes to be brought to the positions shown.

The short-circuiting of the magnet coils may also be effected by the use of two commutators side by side, the segments of which overlap each other (as shown in Fig. 4), to the extent required to bring about the requisite short-circuiting. The necessary removal of the short-circuiting at the start can be brought about either by taking away the short-circuit brushes or by the automatic arrangement shown in Fig. 5.

To prevent too great an increase in current during the short-circuiting, a resistance is provided in the circuit. The same object is gained by using an induction coil, the windings of which are connected to the armature and the magnet coils respectively. The induction prevents a too great increase in current (Fig. 6).

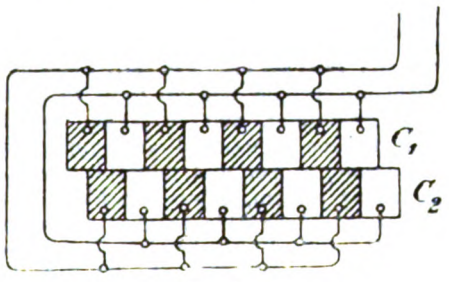

Fig. 4.

This motor has been put up in various places, among which may be mentioned—Wiener Neustadt, three motors of 10 horse-power, and Innsbruck, one motor of 50 horse-power, one motor of 10 horse-power, and one motor of 5 horse-power.

The following abstract of the report of the Committee recently appointed by the Town Council of Frankfort-on-Main to inquire into the alternating and direct systems of distribution will be of interest in this connection.

On the question of the output and efficiency of the Ganz alternate-current motor, the Committee report that experiments were made with the 25 horse-power and 5 horse-power types. The former gave efficiencies of 82 per cent. to 88 per cent. for outputs of 15 to 35 horse-power; the 5 horse-power showed efficiencies of 60 per cent. to 80 per cent. for outputs of 3 to 8 horse-power, the figure for normal load being on an average 78 per cent. The efficiency, therefore, does not differ to any important extent from that of direct-current motors.

With respect to starting, it was found that the 25 horse-power motor could not start itself, and the smaller sizes, 5 horse-power and $\frac{1}{3}$ horse-power, were unable to do so in certain positions. A test as to starting the motor with full load on was not made, as Messrs. Ganz and Co. objected to it. The time necessary for the attainment of normal speed was from 30 to 45 seconds. The start was always accompanied by heavy sparking at the brushes, diminishing as the normal speed was reached. In the 25 horse-power machine these sparks were 5cm. long, and 3cm. on the 5 horse-power machine. At normal speed the sparking was not worse than with direct-current motors.

With regard to noise, the Committee pointed out that from the nature of the action, as well as from the sparking, when not running synchronously more noise was to be expected from the alternating-current machine. In factories and on tramcars this noise was unimportant; but it would exclude the larger sizes of the

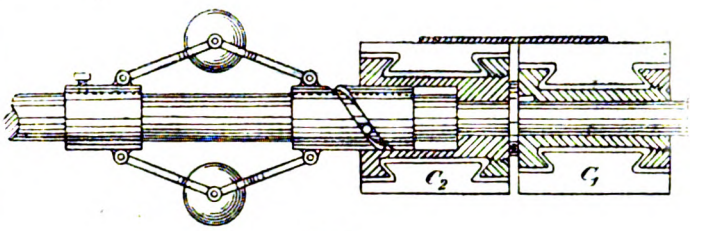

Fig. 5.

motor from dwelling houses, unless exceptionally good foundations were secured. With the small motors the noise would not exceed that of the machines used to drive sewing machines with. The motors being synchronous, regulation of speed could only be arrived at by means of multiple-speeded pulleys.

A series of tests was made to ascertain the effect of sudden application of load and of overloading, and it was found that the 25 horse-power motor did not fall out of synchronism till it was loaded with 40 horse-power, and the 5 horse-power motor could be loaded up to

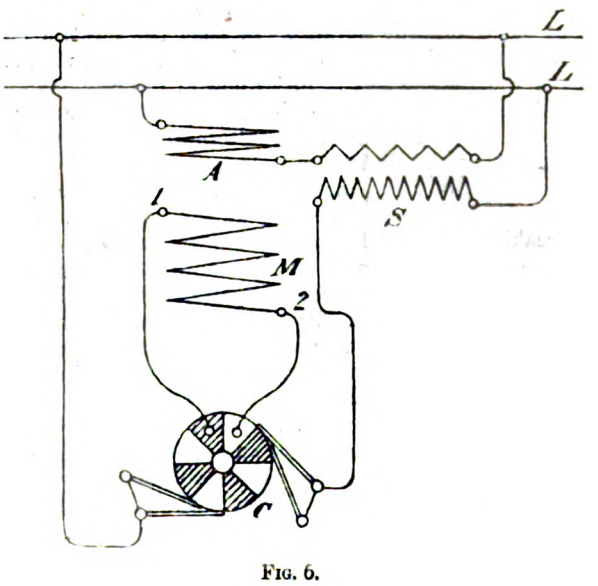

Fig. 6.

8 horse-power, in each case a maximum load 60 per cent. in excess of the normal. A sudden load of 26 horse-power can be put on to the large machine when running light, though a heavier load than this suddenly applied will cause it to stop. When running at 26 horse-power a further sudden load of 8 horse-power, and after the application of this a further 6 horse-power, can be put on, the total load being then 40 horse-power. The whole of this load can be suddenly removed without affecting the behaviour of the machines. The 5 horse-power machine could take a sudden load of 6 horse-power, which in the same way could be suddenly increased to 8.

These tests show that the normal output must be kept well under the possible maximum, or, in other words, that a considerable margin must be allowed in settling on the size of machine to be employed. It should be mentioned that the machines tested were the second of their respective classes that had ever been made.

THE WEYMERSCH BATTERY.

A demonstration of the capabilities of the Weymersch battery for electric lighting on a small scale is now being made at the offices of the Weymersch Electric Battery Syndicate at 2, Victoria-mansions, the offices of the Syndicate being lighted by several incandescent lamps, and a 400 candle-power Planet arc lamp run off Weymersch cells. The Planet lamp is run directly off a battery of 30 cells, and works very satisfactorily. M. Weymersch's depolarising solution is sold at one shilling per gallon, from which quantity of liquid about 1000 watt-hours of useful work may be obtained under ordinary working conditions; so that a 30-watt lamp can be run off this battery at a cost for depolarising solution of about ½d. per hour, or about ¾d. per hour taking everything into account. A full description of the Weymersch battery appeared in *The Electrician* of June 28, 1889; and Messrs. Alabaster, Gatehouse and Co.'s report will be found in *The Electrician* of June 22, 1888.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *February* 22, 1890.

Meeting of the National Electric Light Association at Kansas City.—The National Electric Light Association has just held, at Kansas City, its 11th semi-annual meeting, with so large an attendance that everyone interested in the Association is well satisfied at the results of the somewhat risky plan of holding a meeting in the winter in the south-western corner of the country, remote from the homes and businesses of a large majority of the members. The papers that were read were, with few exceptions, of the usual practical nature. One of the most important presented was that by Prof. Elihu Thomson, who took up the subject of "Safety and Safety Devices in Electric Installations." In this Paper Prof. Thomson took the trouble to point out that while we all know that the electric current may be a source of danger to life and property, it may also, by means of the devices and facilities now at the command of the electrical engineer, be made thoroughly safe. The question is not one of direct current or alternating, low tension or high tension, overhead wires or underground wires, but belongs to the province of right methods, and the use of such insulation and other protective devices as will prevent the service from breaking down or developing dangerous conditions. With regard to subway circuits he advanced a somewhat novel theory to account for the recent explosions of which we have had so many in New York City. A heavy leak or overheating, he says, occurring at some point of the conductors near the manhole may generate directly a large volume of inflammable gas from the distillation of asphaltum or other substance used as an insulator; and this gas, mixing with the air of the manhole, may be easily fired by the heat of an arc or spark subsequently to its production, and cause a violent explosion. The remedy is thorough and continuous ventilation of the spaces in the manholes and subway. With regard to interior wiring, he approves such methods as those recently worked out by the Interior Electrical Conduit Company, as described in my letter some time back; and with regard to methods of incandescent light distribution he deemed such to consist in a "properly arranged double wire cable, well insulated, constituting the primary line, laid in ventilated pipes underground, transformers connected therewith, also enclosed in a grounded metal case, in the cellar of a building, and a secondary line of low potential grounded or provided with safety devices, as mentioned."

Another subject that was taken up was that of mutual insurance, on the lines of the new company to which I have previously alluded. Attention was called to this scheme by the report of the committee on the subject, and it is now understood that already some 49 stations, representing an insurance risk of upwards of one million dollars, have signified their approval of the plan, and their willingness to co-operate. So large a guarantee insures the success of the scheme. In connection with this subject it was proposed in the Association that a committee be appointed to see if, following the example of various sections of the country, a set of uniform rules for insurance could not be adopted and enforced all over the States, so that the work would be of equal standing and efficiency everywhere. Such a committee, working in connection with the insurance people, would constitute a body to which could be referred important questions for final adjudication, and its careful work would be of vast benefit. The idea was generally approved, and it is probable that something of the kind will soon be attempted.

Another subject of general importance which was brought up was that of potentials for electric railways, this being a matter in which not a few electric light companies are directly interested, and which is to be considered by the officers interested in electric railway enterprises. With regard to potentials now in use, the committee said that they found them to vary from 220 to 800 volts. The greater number of companies, however, reported using a potential between 450 and 550 volts. The committee were glad to be able to report that they had written authority from both the Thomson-Houston and Sprague electric railway companies to make a statement on behalf of their respective interests, that they will hereafter agree to use a standard potential of 500 volts upon all electrical street-railway equipments that do not require any special apparatus for their successful operation. The committee recommended the electric light companies to add to their regular business the furnishing of power to street railroads, but wish it distinctly understood that they do not base any hopes of profit on the old idea that the same machinery could be used for furnishing light, heat, and power in the daytime. Their suggestion is, that while the station itself may thus be in continuous operation all the time, different sets of apparatus, specifically built for the work it is intended to do, should be provided. A great saving for the central stations would lie in the reducing of labour and fixed charges over the whole work, and in the fact that the reserve power for the one service, though not the plant actively engaged, would suffice for the other. It appeared from the report of the committee, that, so far, only nine of the electric light companies had been enterprising enough to agree to supply the street-railway companies with their power, although in nearly every case where the railroad had been put into operation, there was, at least, one central station that could well have contracted to supply the necessary current.

A very interesting address touching upon the electric railway subject was also delivered by Mr. Frank J. Sprague, who made a rapid review of the work done during the past two or three years, and then went on to discuss one or two of the leading questions now agitating the electrical community. One of these was the interference between the telephone, electric light, and railway interests, Mr. Sprague contending that the telephone people had no right to a monopoly of the earth for grounding, and that, as the electric railway service had been sanctioned and approved by public authorities as a safe, proper, and desirable method of travel with a single trolley system, it was not likely that the telephone companies would be able to check the progress of the new industry. He showed how the electric railway companies had already won several contests, and remarked that, with the records thus gained, it would seem that the electric railway companies had little to fear from the telephone interests, being well within their rights. At the same time he suggested that in a great many instances reasonable and satisfactory methods of compromise might be resorted to. With regard to the future Mr. Sprague remarked that we had already got beyond the stage of operating three or four cars in the street, and even beyond that of running 40 or 50 cars from the central station, the next step being the providing of such systems as the underground railway of London or the elevated railways of New York. With regard to the trunk line service, he went into a very interesting discussion, and made the rather striking point that for running between New York and Philadelphia, for instance, the aggregate of the copper already in use for the long-distance telephone service is 40 per cent. more than the weight of two copper rods an inch in

Digitized by Google

diameter for electric railway service running between the two cities! "If the investment is a reasonable one in the telephone system," he says, "cannot we consider it a reasonable one in that larger field of transmission of power of which we are now speaking?" He then went on to discuss the probabilities involved, and led up to the conclusion that it would be thoroughly practicable to operate a 60-mile express service every ten minutes between New York and Philadelphia, instead of a 40 or 45 miles' service every hour. Such a change would revolutionise travel, and would develope a great many conveniences of a kind now undreamt of. In the subsequent discussion, Mr. Sprague made a statement that he and some friends of his had recently invested in an electric road in the South, and that they had also bought up the electric light interests, and consolidated the elements of manager and *personnel*. He thought it possible they might even control the telephone interests, and they propose to run the telephone wires on the same poles with all the other circuits. "We are going," he said, "to demonstrate that it is quite possible to run the telephone circuits and the electric railway pole line not only in conjunction with it, but in conjunction with electric lights and incandescent lamps. We hope this enterprise will be profitable, and that there may be a great many other places in which the same thing may be done."

Two very interesting Papers were presented on the subject of arc lighting, one on "How to make Arc Light Circuits Safe," and the other, by Mr. Law, entitled "Nine Years with the Arc Lamp." There was a third Paper on a kindred subject, that by Mr. Peck, on "Carbon Tests." Mr. Law in his Paper showed how desirable it was for station superientendents and managers to study out their lamps in their details, and to see where they could make little improvements for themselves with the result of greater efficiency in service and economy in construction. Mr. Law touched upon many points that may seem small, but yet are important; for example, he said the waste in the use of carbon is a very important feature. These should be dealt out, and every stump returned. The amount saved in laying by the four or five inch stumps to be used in the summer months will make a saving of at least 10,000 carbons per year for a 1,000-light station. At the time he first started dealing out carbons and bringing in stumps he saved on an average over $30 per month, and then only trimmed about four hundred lamps per day. In the Steam Engineering Department, two or three very interesting Papers were presented, including those by Mr. G. H. Babcock, on "The Economical Generation of Steam for Electric Light Stations"; Mr. C. J. Field, on "The Brooklyn Edison Station"; Mr. C. J. H. Woodbury, on the "Construction of Central Stations," and Mr. F. Sickels on "The Steam Engine," the last named author, as some of your readers may know, being one of the predecessors and competitors of Corliss, well known from his connection with the trip cut-off valve which has now been before the public for well nigh fifty years. The most important part in Mr. Field's Paper, apart from his statements with regard to the Brooklyn Edison station, which I have already noted in my letters, was his reference to the triple expansion engine imported from France by Mr. Edison.

Two other interesting Papers were those presented by Mr. A. J. De Camp and Mr. T. C. Smith, on the subject of "Central Station Accounts." There were a number of other topics touched upon, but I have mentioned enough to show the range of useful discussion.

CORRESPONDENCE.

TESTING GALVANOMETERS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR,—Messrs. Elliott Bros.' letter in your issue of February 21st is written in such very questionable taste that it appeared to me undesirable to answer it. It has, however, been pointed out to me by several of my friends that my not replying may perhaps mislead those who are not acquainted with the particulars into imagining that there is some foundation for Messrs. Elliott's criticisms of my remarks made at the Physical Society.

As someone has been good enough to draw your attention to certain errors in your report of the meeting of the Physical Society, published in your issue of February 14th, and as you have already published the necessary corrections, it is now obvious that the first half of Messrs. Elliott's letter is a criticism of your reporter and not of my remarks themselves.

In the second half of their letter they make the following statement:—"For the last 25 years at least it has not been customary to use any other cell than the Daniell's in testing for the figure of merit." As far as it concerns their own practice, I have the following certain reason for knowing that this statement has been made by Messrs. Elliott under some serious misapprehension:—Some four or five days before my departure for India, which took place on December 26, 1868, I went by appointment at about four o'clock in the afternoon to see tested an astatic reflecting galvanometer which Messrs. Elliott had constructed for me. On entering, in company with the late Mr. Becker, a small room which was near the front door in Messrs. Elliott's former premises in St. Martin's-lane, there stood on a table against the wall on the south side of the room the galvanometer set up ready for testing, the scale and lamp in position, and between them was a Grove's cell, the porous pot of which, containing the platinum, had been temporarily removed and put into another vessel by the side on the table. While Mr. Becker was turning up the wick of the paraffin lamp, which stood on the scale at the west side of the table, I mentioned to him that, although in the specification that one cell through so many megohms was to give no less than such a deflection, it had not been expressly stipulated that the cell to be used was to be a Daniell's cell, I had certainly understood the specification in this way. He replied, however, that they always used a Grove's cell in testing galvanometers. The whole incident has been ever since very firmly fixed in my mind, as it gave me my first lesson regarding the necessity of minute detail being inserted in specifications to avoid misunderstandings.

It is, therefore, quite certain that, at any rate, 21 years ago it was Messrs. Elliott's usual custom to employ a Grove's cell, and not a Daniell's, in the testing of a galvanometer; and it was on this account that I asked Mr. Mather in January last to write to Messrs. Elliott regarding their tests of one special galvanometer constructed a long while ago, and the maker and tester of which were, I understood, both dead.—Yours, &c.,

W. E. AYRTON.

SECTIONAL CONDUCTORS FOR ELECTRIC TRAMWAYS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In the last issue of *The Electrician* there appears a report, drawn up with a great flourish of trumpets, by three English engineers, on a system of sectional conductors for electrical tramways, which is called "The Wynne Electric Tramway System," by means of which "power is transmitted from the engine to the car as directly as by rope traction without the objectionable necessity of cutting a continuous slot in the roadway." It is mentioned in the editorial remarks on this American system that it does not possess that startling novelty Mr. Wynne and the reporters imagine; but it is not stated that the detailed methods described by Prof. Perry and myself in our patent specifications Nos. 783 of 1881, and 2,395 of 1883, were originated for carrying out several years ago, *by practically exactly the same means, the precise idea* that constitutes Mr. Wynne's invention of 1890; and that therefore, in the expressive language of his country, his proposal is a "chestnut."

The system is for the purpose of working even a long electric tramway, or railway, without the necessity of having either:—

1. The leakage from rail to rail that occurs with a line like the Brighton Electric Tramway.

2. Or an overhead insulated bare conductor rubbed along its whole length by a carrier pulled along the moving car—the system now commonly adopted in America.

3. Or a well-insulated conductor raised a few feet above the ground, and rubbed by a shoe attached to the moving car, as at Portrush.

4. Or a continuous slot on the road, as at Blackpool.

Digitized by Google

The former of the two patents mentioned above, viz., that for 1881, covers and describes methods for attaining this result by the use of:—

"Our improved apparatus consists of an insulated wire, cable, or other conductor or conductors, placed either alongside, above, or underneath the railway, or in any other suitable position, and the insulation of which is maintained by gutta-percha, india-rubber, &c., or by paraffin or other oils, or by its being supported on insulators. This conductor, or conductors, is automatically, or at will by a signalman or other person, electrically connected successively to one or more sections of a rail in the neighbourhood of the moving train. This rail, which may or may not be that on which the train moves, and which may be rigid or somewhat elastic, is divided into sections fairly well insulated from one another and from the earth, &c."

Then it is explained that the insulation of a conductor on the ground, as, for example, the ordinary rail, is sufficient in certain cases to enable it to be used as the sectional conductor, "dividing and insulating the said rail at the usual fish-plate or other joint into sections of suitable length."

The devices described in detail in the 1881 specification for automatically connecting the main well-insulated cable with the various sections in succession of the rubbed conductor are worked mechanically; but, quoting from the patent:—"We do not restrict ourselves only to the specified means of effecting contact between the rubbed rail and the well-insulated conductor, inasmuch as our improvement consists essentially in employing only a short part or parts of the sectionally-insulated rubbed rail as conductors at any one time, viz., those to which the travelling carriage is nearest." Further on, this specification states, "Instead of the mechanical plungers we may use electric means for this purpose . . . or we may employ a magnetic arrangement depending for its action not on the weight of the train, but on its magnetic mass." This latter is the plan *subsequently* brought out by Mr. Binswanger, and published some three years ago.

The second of our two patents referred to above, viz., 2395 of 1883, the provisional specification of which is illustrated with 24 drawings, and the final with 31, is wholly occupied with descriptions of numerous methods for carrying out Mr. Wynne's idea of automatically, or at will, making a connection *electro-magnetically* between the well-insulated conductor and one or more of the sections of the rubbed conductor which are in the neighbourhood of the moving train.

This specification even describes, in the following words, Mr. Wynne's device of using a battery carried on the moving car for re-establishing contact between the well-insulated conductor and the sectional conductor:—

"For this reason we prefer for railways on the ground not to replace our automatic mechanical contact makers by electrical contact makers operated by the mere short-circuiting action of the wheels or brushes on the train, but instead a current—to use accumulators, or a battery, or a small magneto or dynamo machine on the train to operate the contact maker; or, lastly, to arrange that the short circuiting of two things at any contact-box can only put current on to a section if the current has already been supplied to the previous section—that is to say, although the successive short-circuiting action produced by the train at each contact-box will, in succession, connect the next section with the main supply cable, and disconnect the last section, the short-circuiting of certain things at any one contact-box at random will produce no effect whatever." And as a further proof of the striking similarity between our devices of 1883 and Mr. Wynne's of 1890 we may quote the following, which occurs in the same specification after the account of the detailed methods adopted for working the contact-boxes by the battery carried on the train:—

"It is to be observed that although a train which has been at rest in any section can by one application of the battery it carries cause at will the main supply cable to become connected with that section, and as it proceeds along it can, without any further application of the battery, connect the supply cable with every section in succession, disconnecting it in succession from every section left, no mere random short-circuiting of the end and beginning of the rails of any two sections, or of the insulated and earth rail of any one section—by means of a crow-bar, for example—can produce any effect at all."

In the report on Mr. Wynne's system, stress is laid on the fact that by connecting two adjacent sections in parallel with the rubbed conductor, so that the circuit through one section and the motor on the train is closed before the circuit though the section behind is broken, Mr. Wynne obtains an arrangement which "effectually obviates sparking." I have again merely to quote the following from our patent 783 of 1881:—

"When a carriage, or train, in the ordinary course passes from one section to the next, whether going forwards or backing, the main current, as already explained, is put on to the section the carriage, or train, is entering before it is taken off from the section the carriage, or train, is leaving; indeed, it is not until the carriage, or train, has received the current on the section just entered that it is taken off from the section being left, and for a short time while the carriage, or train, is partly on one section and partly on the other, it is receiving current from both sections; and we have adopted this arrangement partly in order that the induced sparks or flashes that are usually produced in making or breaking an electric circuit, and which rapidly burn away the contacts, shall not be produced by our form of contact makers."

No one admires the go-aheadedness of the Americans more than I do; but, when an idea of pure British origin returns across the Atlantic with so strong a Yankee accent that it might well pass for having been born and bred in the States, one feels that that is going ahead just a little too fast.—Yours, &c.,

W. E. Ayrton.

THE WYNNE SYSTEM OF ELECTRIC TRACTION.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: I should like to make a few remarks on the note in your last issue referring to my system of applying electricity to the working of urban tramways.

From your note it might be supposed that, having worked out a scheme on paper, I at once rushed into print; this, however, is very far from being the case, as, with your permission, I will proceed to show, and also to show that my claim to novelty is fairly well founded. The first patent dealing with rubbed sectional conductors is, so far as I am aware, Prof. Ayrton's, No. 783, 1881, in which he proposes using them for electrical railways for the expressed purpose of reducing leakage of the current, and he employs a sectional insulated rail made slightly elastic and furnished with mechanical plungers, through which, by the effect of the weight of the passing train, contact is made with the main insulated conductor. Dr. Hopkinson, in his patent No. 4,718, 1882, refers also to the use of insulated sectional conductors on electric railways for the same purpose of preventing leakage, and he employs the rise of potential caused by the car coming on the new section to make the connection between the main conductor and these rubbed insulated sectional conductors.

My first patent for applying electricity to tramways is dated April 9, 1883; and in that patent the special advantages of short-rubbed road-bars for electric tramways, as opposed to electric railways, is for the first time fully described, and the principle of using short lengths of sectional uninsulated exposed road-bars—charged successively—and short enough to ensure the ordinary traffic of the street being secured, by the protection of the car, from accidental introduction into the electrical circuit, is first developed; details are also given of an automatic electric system, whereby the short lengths may be successively charged from an insulated main conductor. Prof. Ayrton followed with his patent No. 2,395, 1883, for electric railways, being a continuation of part of his patent, No. 783, 1881, and describing a method of effecting the successive charging of his insulated sections ("a mile or more in length") by causing a momentary short-circuit as the train enters a new length. In my patent, No. 9,215, 1886, for electric tramways, I provide for an even greater subdivision of the rubbed road-bars than in my earlier patent, and amongst other things I show a contact-maker actuated by an electro-magnet carried by the car.

Digitized by Google

Messrs. Pollack and Binswanger, in their electric tramway patent No. 14,106, 1886, adopt my principle of making the rubbed road-bars short, and thus protecting the ordinary street traffic from contact with the charged sections; they effect the successive connection of these short road-bars to a main insulated conductor by means of an electro-magnet carried by the car, and which acts by induction on contact-makers in the roadway.

In my patent No. 747, 1887, or more than three years ago, I show another way of connecting these short protected lengths of road-bar successively to an insulated main. In this system there is no limit to the power available for making the contacts good.

For all the above inventions patents have been granted, both in the United States and in Germany, which may be taken as a fairly satisfactory proof of novelty.

Mr. Wheless, to whose system you referred, is, I submit, open to the reproach—if it be one—of having rushed into print with a Patent Office specification, his patent dating only, I believe, from the latter part of last year.

The question of possible trouble with so large a number of contacts forms the subject of a special paragraph in the report of the Brush Electrical Engineering Company's Engineers, lines 27-35 (page 427 of your issue of February 28th); and besides this I may refer to Sir Frederick Bramwell's report to the directors of the Series Traction Syndicate, and dated April 16, 1889, on a similar supposed difficulty in connection with the number of contacts in what is known in America as "The Short Nasmyth Series System." (*See* extract below.) There is no sparking whatever in my contact boxes My patent of 1886 was followed by long and complete trials on a full-gauge line at Messrs. Elwell-Parker's works; but nothing was published, as they resulted at the time in only partial success, although in a great deal of hard-earned experience.

Before submitting the system described in your last issue to the notice of the engineers of the Brush Electrical Engineering Company, I had profited by the criticisms of some of the best-known tramway engineers, whose advice I had the advantage of obtaining.

I wish it to be clearly understood that I do not make any criticism, favourable or unfavourable, on other systems; but I may mention that it was with a full knowledge of what I had done, and of what had been done by others, that the engineers of the Brush Company expressed the opinion "*that it is the only practical attempt that, up to the present, has been made to grapple with the real difficulties of urban electric traction.*"—Yours, &c.,

FRANK WYNNE.

5, Westminster-chambers, March 5, 1890.

Extract from Sir Frederick Bramwell's Report.

"As regards the probability of this electrical conductivity being maintained, no doubt it is a somewhat startling proposition that, at every 21 feet in a line of tramway, contact should have to be broken and made on the passage of every car. But also, if, up to this day, although clocks were well known, watches had never been used, it would be a startling proposition that a timekeeper on the principle of a clock could be made so that it could be carried in the pocket, and, while being thus subjected to all the jars and concussions arising from its wearer walking about, should nevertheless work successfully and keep good time. Yet, startling as this proposition would be, if made now for the first time, its daily practical fulfilment is looked upon as one of the commonest of accepted facts. Moreover, in the event of any spring-jack getting out of order, it is but the work of a few minutes to make electrical connection past it, with the result that the cars by their momentum travel over a section thus thrown out of use without appreciable loss of speed."

COST OF ELECTRIC TRACTION ON THE BARKING ROAD.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have delayed commenting on your remarks on my letter of 10th ult., in order to see whether any of your other readers would take up the subject. As, however, no letters have appeared, I beg to send you the following figures as forming the basis of my "scepticism."

As the average tractive effort required on the level, I have taken the figure usually adopted, 30lb. per ton. Considering that the Barking Road line, though fairly straight, has a number of sharp turn-outs for passing places, and that the rails are not in the best order, I am convinced that this figure will not be found too high by any means. Taking this value for the tractive force required, it will be found that a car is capable of travelling by its own weight down a slope of about 1 in 75. Therefore, on lighter gradients than this the extra work expended in going up hill will, theoretically, be compensated by a corresponding saving when going down; but on steeper gradients this compensation will not be complete, as to make it so we should have to make the action of gravity put back work into the accumulators. This, of course, is not done, and the consequence is an expenditure of work on up-and-down gradients exceeding 1 in 75, greater than the average. (I may mention that in practice extra average work is required on *all* gradients, not only on those on which the theory would lead us to expect it.) Now, on the line in question the following gradients occur:—200ft. of 1 in 66, 450ft. of 1 in 56, 360ft. of 1 in 40, and 325ft. of 1 in 36, all of which give rise to this increased demand on the accumulators. Making the requisite addition on this head, allowing 12 starts and stops on the double journey of 2½ miles (deducting an amount corresponding to the distance run after cutting off the current in stopping), I find that an accumulator car, weighing with an average load of passengers eight tons, requires for the 2½ miles an expenditure of 3,650,000 foot-pounds of work at the car axle, *i.e.*, ·737 horse-power hours per car mile.

Now, as to the efficiency of the system. That of the motor and gearing cannot be higher than 75 per cent., as a motor used for traction is, as a rule, working far below its normal capacity. That of the accumulators I put at 66 per cent., certainly as high as can possibly be expected for the high and variable rate of discharge called for. The efficiency of the dynamo may be put down at 90 per cent., and I allow 10 per cent. for loss in engine and belting. This gives for the efficiency of the system 40·5 per cent., and the ·737 horse-power hours necessary per car mile at the car require a production of 1·82 horse-power hours at the central station per car mile run. The cost of this, including coal, water, wages, depreciation on engine and sundries, is at 1d. per horse-power 1·82 pence. Depreciation on dynamos and switch boards at 7½ per cent. per annum will amount to ·085 pence per car mile, and drivers' wages to ·6 pence.

With regard to maintenance of accumulators and motors, I maintain that no reduction on the costs of these items at Brussels is possible. It is true, as you pointed out, that the Brussels line is more difficult than that at Barking, and also that the rate for renewals would be lower over here; but, on the other hand, it must be remembered that the Barking-road cars are much heavier and carry more passengers than those in Brussels. Then any expectation of effecting a saving by using English plant cannot come to much in view of the fact that the motors ultimately used in Brussels were supplied by an English firm, and that Julien's accumulators were soon discarded in favour of the Faure-Sellon-Volckmar cells.

Adhering, then to the figures originally given, the minimum cost for electric traction on the Barking Road must amount to over 5d. per car mile, made up as follows:—

	d.
Steam power, including depreciation on engine and wages	1·82
Depreciation on dynamo, &c.	·085
Drivers' wages	·6
Maintenance of accumulators	1·5
,, ,, motors	1·0
Total per car mile	5·005

without counting interest on capital.

I am aware that it has been stated that figures can be used to prove anything, but in the absence of facts, I think we are justified in relying on figures if they are put together with some regard to common-sense.

Apologising for the length of this letter,—Yours, &c.,

H. J. S. HEATHER.

18, Stanley-road, Wimbledon, March 1, 1890.

[As our correspondent rightly observes, figures may be made to prove anything, and the following figures, derived from a

Digitized by Google

letter of Mr. A. Reckenzaun's, which appeared in *The Electrician* of August 23, 1889, illustrate this very well :—

	Pence per car mile.
Renewal of accumulators	1·0
,, ,, motor and gearing	·75
Cost of fuel, attendance, maintenance and depreciation of the engine, boilers and dynamos, at the charging station	1·64
Total	3 39
Adding for driver's wages, according to our correspondent's estimate	·6
We get	3·99

A difference between our correspondent's figures and those of Mr. Reckenzaun of over one penny per car mile.—Ed. *E.*]

THE LIFE AND EFFICIENCY OF GLOW LAMPS.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: In reply to Mr. C. J. Robertson's question, I may say that the pressure at the lamps never falls below 98 volts or exceeds 100 volts. The latter E.M.F. is the usual difference of potential. I have hundreds of lamps which have run over 3,000 hours. The one selected for your contemporary was merely a chance lamp, and not a picked one. I attribute the length of lamp life here entirely to my method of obtaining constant E.M.F. (within 1 per cent.) on the lines; and the results have far exceeded my expectations. I find by a Bunsen photometer that 16 candle-power 100 volts Edison-Swan lamps give on an average 15 candle-power at 98 volts, and 17 candle-power at 100 volts; but there are variations to the extent of 1 candle-power in many cases.—Yours, &c.,

David Salomons.

Broomhill, Tunbridge Wells, March 6, 1890.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: The remarks which you make in your "Notes" upon my letter in last week's *Electrician*, on the "Life and Efficiency of Glow Lamps," were matters of which I was cognisant when inditing my letter; but your remarks do not at all lessen the value of my recommendation for referring the life of glow lamps to some standard of efficiency (say, 3½ watts per candle-power, or a fixed temperature). This is chiefly because of the fact that if any lamps were running at their most "economical efficiency," *i.e.*, that efficiency required to minimise the working expenses which you refer to, and if they had either to be referred back or forward to a fixed standard of efficiency, then, their life, at any other efficiency best for economy, would be proportional (other things being equal) to their life at the recognised standard of efficiency.

I agree with you that it would be unfair to compare all lamps under the condition of constant efficiency—but only in the monetary sense, for such a comparison would still be fair as regards life. I think that I was one of the very first to notice and point out the fact of there being a best efficiency at which to run lamps, according to local and other variations in the price of electrical power and lamp renewals. I personally made the necessary experiments, and gave my results to Prof. Ayrton, and the same formed the basis of a Paper entitled "The most Economical Potential Difference to employ with Incandescent Lamps," which was read by Profs. Ayrton and Perry at the Physical Society, February 28, 1885, and published in *The Electrician* of the same or the following week.—Yours, &c., C. J. Robertson, A.I.E.E.

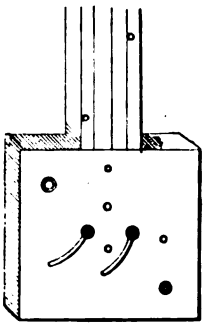
Middelburg, Holland, March 3, 1890.

[Our correspondent's reasoning about the life of lamps is not very clear, but his suggestion is valuable, the only difficulty being in getting the necessary data.—Ed. *E.*]

RIVAL BACK BLOCKS.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: In your issue of February 21st you gave us an illustration of an improved back block. Though doubtless very nice-looking, I must respectfully say I cannot possibly perceive any improvement on the back block of which I send an illustration. This consists of only one block, which is made of hard wood, and can be either turned or left square. A groove is then cut in the block exactly the width and thickness of the casing, and is taken half an inch lower than the centre of block, the blocks in every case being the thickness of the casing and cover, so that when the casing is placed tightly in the groove the cover fits down square on the top part of the block and flush with the front, as shown in the figure. The



casing is fixed to the block by three small screws. Two holes, through which the wires pass, are bored the same distance apart as the grooves in the casing. The advantages of this block are that it can be fixed a little below the plaster—the block being perfectly damp-proof, the wires take no hurt; it can be easily and quickly made, and quickly fixed, and in instances where the casing is on the face of a wall, the block may be turned and polished, which gives it a finished and compact appearance.—Yours, &c., J. J. Hine.

Thorpe, Chertsey, February 22, 1890.

THE CITY OF LONDON AND SOUTHWARK SUBWAY RAILWAY.

On Wednesday, on the invitation of the Chairman and Directors of the City of London and Southwark Subway Company, the Lord Mayor and a large number of gentlemen connected with railway and commercial undertakings made a trial trip over this railway. For the purposes of the trial trip an engine and a couple of carriages were brought into requisition. The run down to the "Elephant and Castle," which is about a mile and a-third in point of distance, was accomplished in a little over four minutes. Arrived at the Elephant Station, Mr. Greathead, the engineer, gave some interesting particulars concerning the way in which the work had been carried out.

The chief features of interest having been explained to the Lord Mayor and the party, the visitors took their seats for the return journey; but the train would not start. It was explained that the mishap had nothing whatever to do with either permanent way, locomotive, or the electric generating appliances, but was owing simply to the fact that the turncock of the Southwark and Vauxhall Water Company refused to "turn on" the water required at the generating station. After being kept at the station for something like an hour over the time laid down in the programme, the train ran swiftly back to King William-street.

The party then partook of luncheon, laid out in a large room forming a portion of the offices of the Company at King William-street. The chair was taken by Mr. G. C. Mott, the Chairman of the Board of Directors of the Company, and he expressed his regret at the misadventure that had occurred which had necessitated the absence of some of their distinguished guests.

Lord COBHAM said that, although there was no regular list of toasts, he was desirous of proposing "Success to the City of London and Southwark Subway Company." He said the undertaking that the Directors of the Company had under their control was one of the most novel description. He believed that such a system would meet a great necessity, and he called upon them to acknowledge the efforts of Mr. Mott and the other Directors of the Company who had been foremost in the movement.

The CHAIRMAN, in acknowledging the compliment on behalf of himself and his fellow-Directors, regretted the delay that had occurred in consequence of the action of the Southwark and Vauxhall Water Company in cutting off the supply of water to the engine. After giving some interesting statistics with regard to the growth of street traffic in the metropolis, Mr. Mott expressed the thanks of the directors to Dr. Edward Hopkinson and Dr. John Hopkinson, the electricians, for the admirable way in which they had worked,

Mr. MATHER, M.P., in acknowledgment of what the Chairman had said, remarked that the Directors had shown their confidence in the undertaking by calling them together before the absolute completion of the work. He trusted that by means of these railways the congestion of traffic in London would be overcome, and that the public would in future be able to travel with much greater comfort than they could now.

The proceedings then terminated.

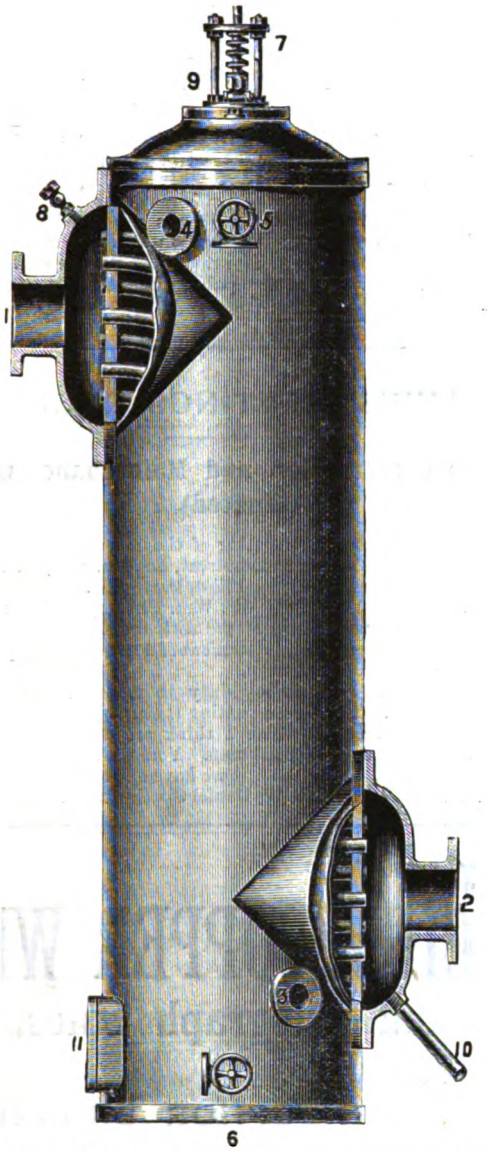
THE "COMPACTUM" FEED-WATER HEATER.

The apparatus described below (which is specially designed for high-speed and other electric light engines) consists of a cast-iron casing fitted with a number of solid-drawn brass S tubes, through which the exhaust steam passes. The ends of these S tubes are securely fixed in tube plates formed in the case, which, while keeping the ends tight, allows the body of the tube to expand; these tube ends can be easily got at by removing covers and one length of exhaust pipe, without disturbing the heater. The feed-water is pumped through the heater, entering at the bottom and passing out at the top to the boilers, being heated on its passage through, and depositing its scale and grease in the heater; the former falling down clear of the tubes, can be blown or scraped out from time to time. An arrangement is provided for the extraction of air and grease. There is also a connection on the exhaust outlet cover to take away the condensed steam, thus relieving the back pressure and giving a supply of hot fresh water, which can either be used over again as feed-water or for a variety of other purposes. The top cover and bottom sludge doors are easily removed, thus allowing for tubes to be readily got at for cleaning



1, Exhaust inlet; 2, exhaust outlet; 3, feed inlet from pump; 4, feed outlet to boilers; 5, scum valve; 6, drain and sludge valve; 7, relief valve; 8, soda cock; 9, soda and air cock; 10, drain from tubes; 11, cleaning door.

purposes. The apparatus is of moderate weight and dimensions, and no special foundations or brickwork are required, while the cost of fitting is smaller than for other heaters.

The use of this apparatus ensures economy in working, as with a little attention it will, in addition to heating the feed-water, remove nearly all the solids, grease, and air, thus saving the costly cleaning and dangerous deposits so common in feed-waters. The "Compactum" is specially designed for applying to the exhaust of high-speed engines for driving dynamos, &c., and it is claimed by the manufacturers, John Kirkaldy (Limited), of 40, West India Dock-road, London, E., that the large amount of heat which is imparted to the feed-water on its passage through the heater causes a saving of at least 15 per cent. on the expenditure in the boiler department. Our readers will readily appreciate this great economy in working.

Messrs. Kirkaldy make a speciality of feed-water heaters and condensers for all purposes, and it may be said for the "Heater" under notice that it has been designed and constructed upon scientific lines.

TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning.*]

RESULT OF TENDER.—At the meeting of the London Council on Tuesday, the Council Chamber and Offices Committee stated that they were of opinion that it would be desirable to adopt the electric light for the new Council Chamber at Spring-gardens. They had been in communication with several electric lighting firms, and had obtained estimates of the cost of installation. The estimate they thought the most favourable, having regard to the amount of light to be afforded and other details, was that of Messrs. Strode and Co., the amount of the estimate being £208. They recommended "That the electric light be adopted for the Council Chamber at Spring-gardens, and that the work be entrusted to Messrs. Strode and Co. to carry out upon the basis of their estimate." This recommendation was adopted.

ELECTRIC LAUNCHES.—We learn that Messrs. T. B. Seath and Co., Rutherglen, have secured an order for four electric launches from Messrs. Morton and Williamson, Glasgow, acting, it is understood, on behalf of the Electric Traction Company in London, who will themselves supply the electrical apparatus for propelling the launches. They are intended for service on the Seine.

SALES BY AUCTION.—Messrs. Wheatley Kirk, Price, and Goulty will sell by auction during the present month a quantity of modern engineering machine plant, tools, and stores. The sale will take place at the Works, 417, Old Ford-road, London, E. Particulars will be found on page 3 of Advertisements.

——— Messrs. Smith and Ford announce the sale on Monday, March 10th, at Battersea, of boiler, vacuum pump, foundry crane, steel shafting, chemicals, and the contents of a chemical laboratory, including gas apparatus, furnaces, &c.

THE UNITED ASBESTOS COMPANY.—This Company have removed their chief offices from 161, Queen Victoria-street, to the Dock House, Billiter-street, London, E.C. We have received from the Company two neatly printed pamphlets, the smaller of which contains illustrations of their mills and offices and particulars of their various manufactures. The larger pamphlet gives a quantity of information respecting the asbestos, &c., goods manufactured by the United. A portion of page 27 is devoted to the electrical department, from which it will be seen that a number of articles in everyday use by electrical engineers are manufactured by the Company, which claims to be the only asbestos company in the world owning and working asbestos mines both in Canada and in Italy.

DISSOLUTION OF PARTNERSHIP.—Messrs. Price and Belsham, of 52, Queen Victoria-street, London, E.C., have dissolved partnership.

"THE ELECTRICIAN"

ELECTRICAL TRADES' DIRECTORY & HANDBOOK for 1890

The new edition of our well-known Directory and Handbook is now ready. The book consists of 850 pages, and has entailed this year an exceptionally heavy amount of work. The HANDBOOK DIVISION contains a mass of most useful information. The DIRECTORY DIVISION consists of more than 400 pages, and contains a very carefully compiled Alphabetical and Classified List of Firms and Persons engaged in the Electrical and Allied Trades in all parts of the world. This Division has been corrected up to date, and the book is thoroughly reliable, even the very numerous changes which take place in the month of January being incorporated. The book is not a mere list of Members of Scientific Societies repeated again and again. The Colonial and Foreign Division will be found extensive and reliable. The book has been very favourably reviewed by the Press. *Orders should be forwarded at once.*

WESTMINSTER ELECTRIC SUPPLY CORPORATION (LIMITED).—An extraordinary general meeting of this Corporation was held on Wednesday at the Company's offices, 4, Victoria Mansions, London, S.W., under the presidency of Lord Suffield, when alterations in several of the Articles of Association were agreed upon,

LEGAL INTELLIGENCE.

Aron Bros. v. Watson Bros.

In this case, heard in the City of London Court on February 26th, before Mr. Registrar Wild, the plaintiffs, Messrs. Aron Brothers, Bridewell-place, sought to recover the sum of £7, the price of a portable electric lamp supplied to the defendants, Messrs. Watson Brothers, opticians, electrical engineers, &c., of 4, Pall-mall. Mr. Shape, the plaintiffs' traveller, said that in December he called on the defendants, and saw one of them about the sale of one of the plaintiffs' lamps to them. He left a prospectus, and afterwards showed them a lamp. Some little discussion ensued between the two brothers, when one of them gave an order for a lamp.

Mr. REED (for the plaintiffs) said he understood it would be a question whether the lamp burned a certain number of hours.

Mr. KEBBELL (for the defendants): The question is whether it will burn at all. The witness said he examined the lamp, and found it in perfect condition.

Mr. KEBBELL: My defence is that the lamp would not act.

Mr. REED: The simplest plan is to light it.

The REGISTRAR: Are we to sit here for five hours to see if it will burn?

Mr. KEBBELL: The prospectus says five hours to eight.

Mr. REED said they were prepared to prove the lamp would burn from five to eight hours.

Mr. KEBBELL said the intensity of light was to be 25 candles. The lamp was returned as it had never burned for two hours, and the light was very bad during that time.

Mr. SHAPE said he offered to give the defendants every possible assistance to show them that the lamp would run the time he alleged. They would not, however, allow him to do anything to it at all. The lamp was returned by the defendants in a defective condition. One of the poles had been knocked off. It was not possible for the lamp to burn without it. In cross-examination, he said he offered to test the lamp. He was not now in the plaintiffs' employment. He did not claim commission on this order. He told the defendants the lamp was the best thing in the world, which was true.

Mr. ARON, one of the plaintiffs, said he guaranteed the lamps. He had been burning them since October. They always burned from five to eight hours, and he had seen some burn ten hours, but they were never less than five. He had never had any complaints before.

Mr. KEBBELL said his case was that the plaintiffs' traveller was anxious for the defendants to buy a lamp, and he recommended it as the best thing out. The defendants, instead of that, found it would not go, and sent it back.

Mr. A. H. WATSON said he was an electrical engineer, and therefore acquainted with these lamps. He had a lot to do with the many different kinds of lamps, but he had not seen this one until the traveller called his attention to it. The traveller said it would burn for five hours. He was particular in asking that question, as many of these lamps would not do that which was stated of them. When the lamp came he carried out the instructions contained in the prospectus. The light they obtained was certainly not 25 candle-power, as represented. An hour after the light had been burning it perceptibly diminished, whereas at an hour and a-half it was practically no use as a light. There was a red glow in the light, but it did not illuminate. He did not refuse to let the plaintiffs' traveller test the light. On the contrary, he said he would accept any suggestions, as he had wasted several hours on the lamp. The lamp was not damaged when he sent it back.

The REGISTRAR said he must find for the defendants with costs. If the defendants, who knew something about electric lamps, could not make it work, how could the public be expected to do so?

Christopher v. Langworth and Others.

This was an appeal, heard before the Lord Chief Justice and the Master of the Rolls, sitting as a Divisional Court, on Thursday, 27th ult., by the plaintiff from a decision of the Court below, striking out, as vexatious and frivolous, the claims of the surviving executors of the late Mr. Thomas Allen, electrician, against the International Telegraph Company to recover the sum of about £1,000,000 sterling. Mr. Thomas Allen was connected with the laying of the submarine cable between England and Holland, and he obtained a concession from the Dutch Government by which he acquired certain rights and privileges. The cable ultimately came into the hands of the International Telegraph Company, and the plaintiffs now alleged that the directors had, by falsifying the accounts, deprived them, as the surviving executors of Mr. Allen, of their proper share of the profits to the extent of about £1,000,000. Their Lordships, after reading the statement of claim, said it was quite evident that the learned judge was right in characterising the action as vexatious and frivolous. There was no proof of fraud whatever, and the appeal would be dismissed with costs.

In re James Fyfe.

On Thursday last week, at the London Bankruptcy Court, a meeting was held before Mr. Registrar Brougham, for the public examination of James Fyfe, described as of St. Stephen's-chambers, Telegraph-street.

The debtor was the managing director of the Pilsen-Joel and General Electric Light Company, and was also part promoter of the Ross Oil Lighting Company, as well as promoter in England for a scheme for lighting by electricity the town of Las Palmas, Canary Islands. The statement of affairs shows liabilities £18,707, of which £1,298 is unsecured, and no available assets.

In the course of examination by Mr. Aldridge, the debtor stated that he had been an electrical engineer for the last 10 years, and the latter part of that time he had acted as managing director to the Pilsen-Joel Company. He had a claim against the Company (which was now in liquidation) for £3,000, but the claim was disputed. He was associated with Mr. Howes and had paid him a certain sum for patents which were now being worked by a Company, and he had a salary for managing the patents.

In the absence of opposition, the public examination was ordered to be concluded.

COMPANIES' MEETINGS & REPORTS.

Telegraph Construction and Maintenance Company (Limited).

The 26th ordinary general meeting of the members of this Company was held at the offices, 38, Old Broad-street, London, E.C., on the 4th inst., under the presidency of Sir George Elliot, Bart., M.P.

The MANAGING DIRECTOR (Mr. Wm. Shuter) read the notice calling the meeting, and the minutes of the 25th ordinary general meeting.

The report of the Directors and statement of accounts (the report appeared in our last issue) were taken as read.

The CHAIRMAN: It is now my duty to move that the report and accounts be adopted. But before putting that resolution I will proceed to address to you a few remarks which I think are due from me on my first appearing before you as your Chairman. You will, doubtless, expect me in the first place to allude to the loss we have all sustained in the death of our former Chairman—the late Sir Daniel Gooch—under whose administra-

tion the Company has enjoyed an unbroken period of prosperity for so many years. I and my colleagues feel that your sympathy and theirs are in common in this lamentable event, and that the resolution passed by us, and which appears in the report, will have met with your entire approval. I next desire to explain briefly the reasons which have induced me to comply with the unanimous request of my colleagues that I should accept the office of Chairman. There are, I dare say, some among you who are aware that I have been a Director of the Company since its formation 26 years since, and that ten years previously to that time I was an original active partner in the business before it became the property of the Company. It would, therefore, be affectation on my part to say that I have not as fair a knowledge of all its working as any individual can have, and I have only to add that I take as keen an interest in its prosperity as I did when it was partly my own property—chiefly, I might almost say. You may therefore rely that no effort will be wanting on my part to ensure its continued success. That success has in my opinion been due hitherto in no small measure to the policy adopted by the Board from the first; that is, while giving the shareholders every information which they could reasonably desire, the Board yet maintained due reticence in regard to business matters, the publication of which might injuriously affect the Company's interests. The shareholders hitherto have accepted this policy, and have placed that confidence in their Directors without which they could not have achieved this success. I trust that in the interests of us all this course may still in a great measure be followed. Of course, there are other causes to which the prosperity of the Company is due, and I should be wanting in fairness to the executive and the staff of the Company if I did not say that it is largely—I would say very largely—attributable to the energy, ability, and industry exhibited by them. My predecessor had perfect confidence in the arrangements and the executive officers of the Company, and I can truly say that I share that feeling I am very glad to say that some of those officers were officers under me when the Company was a private firm. As regards the work carried out during the year, you will judge from the report that we have not much to complain of. Our profits have been largely due to the improvement of our general business other than mere submarine telegraphy. I think that is very agreeable intelligence, because we have something else besides the submarine telegraph upon which we can rely, and which we are trying to extend. As far as we are able to judge at this early period of the year, our prospects appear favourable. We have two contracts in hand—one to lay a cable—it is a large work—between Australia and New Zealand, and that cable is now despatched. The other contract is to renew a portion of the Madras-Penang cable, which next week will have to be carried out. Work is always arriving for us, and I have strong faith that it will continue. Periodically there appears to be no great future for it, but demands always seem to arise and seem to be able to keep us fully employed, or nearly so. We have an excellent staff of agents. We have Mr. Shuter, our Managing Director, and Sir George Richards, and we have an excellent staff who are the strength of our business. I think as far as the cable portion of our business is concerned we stand far, far away unrivalled by any other company. I now propose:—

"*That the report and accounts of the Directors to December 31, 1889, submitted to this meeting be and the same are hereby received and adopted, and that a dividend of 36s. per share, in addition to 12s. interest or interim dividend paid on July 16, 1889, be paid on all the shares of the Company for the year ended December 31, 1889, and such dividend to be paid free of income-tax.*"

Mr. GEORGE W. CAMPBELL: I have much pleasure in seconding that.

The CHAIRMAN put the motion, which was carried unanimously. Continuing, he said: There is another resolution, which relates to our retiring Directors—Sir Thomas Fairbairn, who is not present, and our young friend here, Mr. James Pender, who, I trust, will be a very great help and support to the Board. I move:—

"*That Sir Thomas Fairbairn, Bart., and Mr. James Pender be re-elected Directors of the Company.*"

Admiral Sir GEORGE H. RICHARDS, K.C.B., F.R.S., seconded the motion, which was carried unanimously.

On the motion of Mr. CROFT, seconded by Mr. HEWAT, Mr. John Gane, F.C.A., was re-elected an auditor of the Company for the year 1890, and subsequently, on the motion of Mr. CROFT, seconded by Mr. MACKAY, Mr. Patrick Glegg, of the firm of Messrs. Weldon, Jones, and Co., was elected an auditor in the place of Mr. James Glegg, resigned.

The CHAIRMAN announced the close of the business, and thanked the shareholders for their attendance.

Mr. DOYLE proposed a cordial vote of thanks to the Chairman and Directors.

Mr. HEWAT seconded the motion, which was carried *nem. con.*

The CHAIRMAN: I thank you very sincerely for the cordial and polite manner in which you have proposed this resolution. I hope, although it is some time since we began this business, that we shall still have several opportunities of meeting each other, and congratulating ourselves on a good business and an unvarying dividend.

The proceedings then terminated.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended February 28th amounted to £5,025.

BRUSH ELECTRICAL ENGINEERING COMPANY (LIMITED).—The following circular has been issued to the shareholders of this Company:—"Six months having elapsed on the 10th February since the registration of the Brush Electrical Engineering Company (Limited), the Directors have pleasure in stating that practically the reconstruction has been completed, and that the business of the Company is established on a satisfactory and permanent basis. The total amount of orders received by the Company is very satisfactory, and the prospects for the future are highly encouraging. The works of the Company in London, at Loughborough, and on the Continent are fully occupied, and the extensions of the Falcon Works at Loughborough are making rapid progress towards completion. The Directors have decided, in view of the satisfactory volume of business transacted during the past six months, to pay a dividend on the Preference shares; and warrants for an interim dividend on these shares at the rate of 6 per cent. per annum, from August 10, 1889 (the date of registration of the Company), to February 10, 1890, are issued with this circular. The books of the Company will not be made up until the close of the year, and the Directors reserve the question of a dividend on the ordinary shares until the complete accounts are before them."

CUBA SUBMARINE TELEGRAPH COMPANY.—The estimated traffic receipts of this Company for the month of February were £3,300, as compared with £3,204 in the corresponding month of last year. The receipts for the month of November, estimated at £3,000, realised £3,112.

DIRECT SPANISH TELEGRAPH COMPANY.—The traffic receipts of this Company for the month of February show an increase of £217 as compared with the corresponding period.

EASTERN TELEGRAPH COMPANY.—The traffic receipts of this Company for the month of February amounted to £53,347, as against £54,611 in the corresponding period of 1889, a decrease of £1,264.

EASTERN EXTENSION TELEGRAPH COMPANY.—The traffic receipts of this Company for the month of February were £38,466, as against £37,584 for the same period of 1889.

GREAT NORTHERN TELEGRAPH COMPANY.—The traffic returns of this Company for the month of February amounted to £19,800. From the 1st January to 28th February these receipts amounted to £39,400, against, in the corresponding months of 1888 and 1889, £41,800 and £42,000 respectively.

WEST COAST OF AMERICA TELEGRAPH COMPANY.—The traffic receipts of this Company for the month ended February 28th amounted to £4,500.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The receipts of this Company for the half-month ended February 28th show an increase of £335 as compared with the corresponding period.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended February 28th, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited), were £3,858.

THE NON-CONDUCTOR OF ELECTRICITY.

VULCANISED FIBRE,

PATENTED.

This new material is supplied in two qualities, Flexible and Hard.

The FLEXIBLE is a substitute for Leather, Rubber, Gutta Percha, &c., and is extensively used by Brass Founders, Axle Makers, Hydraulic, Sanitary, and other Engineers, Pump Makers, Carriage Builders, &c.

It makes the best Hot and Cold Water Packings, and for Axle Washers of all kinds it is unequalled.

The HARD is a substitute for Metals, Hard Wood, Ivory, Vulcanite, Ebonite, &c., and is a good Insulator.

Sold in sheets, 5ft. 6in. by 3ft. 6in., varying in thickness from 1-50in. to 1in.

FLEXIBLE, 2/- per lb.; HARD, 2/3 per lb.

FACTORY.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 617.—Vol. XXIV. FRIDAY, MARCH 14, 1890. Price Fourpence.

NOTES.

Encouraged doubtless by their legal victories in connection with Edison's incandescent lamp patent, No. 4,576 of 1879, and the "flashing" patent, No. 4,847 of 1878, the Edison-Swan Company are, we hear, taking steps to enforce their rights under Edison's "feeder" patent, No. 3,880 of 1880. Although it may be said of this, as indeed of almost every other patent in existence, that anyone setting himself to solve the particular problem in question would probably have arrived at the same result; it must be admitted that Edison had at a very early date grasped the difficulties of the case and the best way of overcoming them.

The specification commences with the statement that "where many translating devices for converting electricity into either power or light are arranged upon the multiple arc or derived circuit system, it is essential that, so far as possible, an equal electromotive force or 'pressure' be maintained in all parts of the system. When, however, each set of conductors is run out from the central station in a straight circuit containing a number of translating devices, the pressure when a number of devices are in operation is apt to be greatest nearest the central station, and to diminish gradually toward the end of the conductors, this 'drop' being due to the resistance of the main conductors. The object of this invention is to obviate such irregularity, and to maintain practically throughout the entire system an equal pressure. This is accomplished by using the conductors leading directly from the source of energy as feeding conductors only, placing no lamps ordinarily in the circuit connected directly to the source, placing the lamps or translating devices upon service or lamp circuits, which connect to and are fed by the feeding conductors in such manner that all the lamp circuits are electrically distant substantially from the source of electricity by the same mass of conductor. By so doing the greater portion, if not all, the drop occurs in the feeding conductors, the pressure in the service or lamp circuits being practically uniform at all points." Several variations of the feeder system are then fully and clearly described.

Twelve claims are made, although the whole essence of the "discovery" may be found in those quoted below:—I. The method of equalising the pressure or electromotive force throughout an electric distributive and translation system, consisting in using feeding circuits which connect to and feed into circuits on which are arranged the translating devices substantially as set forth. II. The combination with a circuit containing translating devices of a feeding circuit leading thereto from the source of energy and containing no translating devices, substantially as set forth. IX. The method of laying the conductors in an electrical supply system, consisting in laying them in sets concentrically as explained, each set being connected to the central station at several points, substantially as set forth.

Sir James Anderson's reply to Mr. Henniker Heaton, in the *Pall Mall Gazette* of Monday last, is one of those practical statements of fact which Mr. Heaton is not accustomed to in the House of Commons, and rarely in the public press. The two principal propositions of which Mr. Heaton is the leading expounder and advocate may be briefly described as the purchase of the submarine cables and reduction of the rates by the British Government; or, failing this, the reduction by the existing companies of the tariff to the Far East to one shilling a word—a tariff which he alleges would yield them a profit. As regards the latter, Sir James shows that the out payments alone to the several telegraph administrations between here and Australia—exclusive of the Eastern Extension Company's proportion—absorb no less a sum than 4s. 10d. per word. In order, therefore, to reduce the total tariff to one shilling per word, and leave a proportion for the Cable Companies, the other administrations, many of them those of foreign Governments, would have to forego nine-tenths of their present charges, which they are hardly likely to do. With regard to the idea of purchase, Sir James argues the matter at some length, conclusively showing that, if for no other reason, the objection of foreign Governments to the necessary conversion of a commercial company's offices on their territory into British Government stations is fatal to any such proposition.

The measurements of the specific inductive capacity of various dielectrics, made by Messrs. Safford and Holman, and reproduced in another column, will be of practical importance for telephonic purposes, since they have been made under conditions similar to those usual in telephonic work. No one would think of testing the insulation resistance of a cable intended to work at a pressure of a thousand volts with the ordinary potentials used with a Wheatstone bridge. Although the

Digitized by Google

cable might sustain the pressure, the resistance would be quite different under the two sets of conditions. For a similar reason it is not surprising that the authors have found that the numbers obtained by testing telephonic cables by the ordinary galvanometer methods are quite useless for telephonic work. The inductive capacity is found to vary considerably with the frequency of the current changes. Although the values obtained will be of considerable use for the purposes for which the tests were made, it may, however, be disputed whether the numbers given truly represent the specific inductive capacity of the dielectrics. The phenomena connected with rapid variations of potential in dielectrics are very complicated.

THE dynamo just brought out by MM. REIGNIER and BARY, to which our Paris correspondent alludes, is certainly a remarkable machine from the point of view of output for weight. A ten and a-half kilowatt machine weighs only 578lb., and it therefore gives over 18 watts for every pound of dead weight.

DR. JAMES MOSER'S short Paper, which we print in another column, furnishes an extremely pretty demonstration of what has, we believe, never before been so effectively demonstrated, viz., the probability that a perfect vacuum is a non-conductor, and not, as was quite recently held by some, a perfect conductor. The experiment is such a simple one that we may expect to see it often made use of for lecture purposes.

IN the March number of the *Phil. Mag.* Prof. PERRY discusses the behaviour of twisted strips. These strips must not be confused with the well-known AYRTON and PERRY magnifying springs. They are formed by giving a permanent spiral twist to a straight strip of metal by applying a twisting moment about its axis. When such a strip is pulled in the direction of its axis a small extension takes place, accompanied by a comparatively large rotation of the free end of the strip. The method of multiplication may be turned to practical advantage in many directions. The strips may be made of various sizes, suitable either for weighing-machines where large forces have to be measured, or for delicate instruments, such as thermometers and galvanometers, where excessively small motions have to be rendered visible. At the Newcastle meeting of the British Association, Prof. PERRY showed several voltmeters in which very delicate twisted strips were employed. They seem as well, if not better, fitted for use in measuring-instruments than AYRTON and PERRY springs; but their behaviour is so curious that all attempts at forming a working theory of their action have hitherto failed. The phenomena are exceedingly complicated, and Prof. PERRY'S theory is confessedly incomplete.

IN the same magazine H. DU BOIS describes a valuable research on KERR'S phenomenon, undertaken with the special object of showing the intimate connection between the rotation of the polarised light and the intensity of magnetisation of the body at the polished surface of which the light is reflected. Ellipsoidal-shaped specimens of different metals were taken, the end of each being cut off and the surface polished so as to form a mirror. To avoid optical complication the light was always reflected normally to the surface. The amount of the rotation produced by reflection was found to be proportional to the intensity of magnetisation when the mirror was cut perpendicularly to the lines of force. When the axis of the mirror was inclined to the lines of force the rotation was proportional to the cosine of the angle of inclination. The verification of this law for five different angles is important, as it has not been done before. Experiments were also made to determine the influence of temperature, with the result that for a range of over 200° C. the ratio between rotation and the magnetic intensity was unaltered for either cobalt, iron, or steel. Some slight differences in the case of nickel are easily explained by the fact that the intensity of magnetisation just behind the mirror differed from the measured mean intensity of the magnetised body. That the effect depended purely on magnetisation, and not on the method by which it was produced, was shown by obtaining the same results when residual magnetism alone was used. The variation of rotation with colour was also investigated. The intimate connection between KERR'S phenomenon and FARADAY'S magnetic rotation is clearly shown by these experiments. The rotation produced is dependent on the intensity of magnetisation immediately behind the mirror, and is probably due to the rays of light penetrating a slight distance into the material before the act of reflection is completed.

OWING to the fact that Mr. H. D. WILKINSON has been for some little time past suffering from illness, he has been unable to recommence his interesting series of articles "Letters for Learners and Unprofessional Readers." Mr. WILKINSON starts on Saturday for the Cape of Good Hope to recruit his health; and he hopes to resume the series on his return to England in the summer.

WE have to acknowledge with our warmest thanks the many letters of sympathy we have received in respect to the late Editor of this journal, all of them couched in terms of admiration and regard which a character such as his naturally calls forth. As Prof. CROOKES truly said in moving a vote of condolence last night at the Institution of Electrical Engineers, "he was popular with all who knew him."

Hamburg.—According to the *Elektrotechnische Echo* the Town Council is considering a scheme of electric lighting on the Popp system.

St. Moritzbad.—The large hotels of this town intend to use the water power of the Silvaplana, three miles distant, for supplying a central station.

Oxford.—At its last meeting the Oxford City Council unanimously passed a resolution assenting to the proposed order of the Electric Installation and Maintenance Company.

Testing Galvanometers.—We have received, too late for insertion in this week's issue, a long communication from Messrs. Elliott Bros. in reply to Prof. Ayrton's letter of last week.

The Bakerian Lecture.—The subject of the Bakerian Lecture, which is to be delivered by Prof. Schuster on March 20th, will be "The Discharge of Electricity through Gases."

Digitized by Google

Bolton.—The Corporation has sent out circulars inquiring from the large consumers of gas whether they are desirous of having the electric light. The price will be 10d. per Board of Trade unit.

The Telephone in Germany.—The traffic on the telephone line between Berlin and Breslau is so great that the postal authorities are considering the advisability of erecting an additional wire between these two cities.

Personal.—Mr. Kenneth MacIver, of the National Telephone Company, has been appointed to a position in the London office of the Company; Mr. Chambers, from Leeds, succeeding Mr. MacIver as manager of the Manchester district.

Blankenburg-a-Harz.—The authorities have signed a contract for the lighting of the streets and the public buildings with the Fabrik für Elektrotechnik of Bamberg. The price to be paid for a 16 candle-power lamp is one farthing per hour.

Electric Traction Experiment.—The Directors of the Vale of Clyde Tramway Company have agreed to allow an experiment to be made on their Govan section with some electrical cars, and in a few days it is expected that a car will be running between Glasgow and Govan.

Florence.—The Municipal Council have approved of a contract with the Italian Edison General Electric Lighting Company for the electric lighting of the principal streets in the centre of that city. It is believed that the installation will be completed three months hence.

London Chamber of Commerce.—The following were elected members of the London Chamber of Commerce at the February Council meeting:—National Telephone Company; Frank Suter and Co., electrical engineers and contractors; Isaac Stow (R. C. Cutting and Co.), electrical engineer.

Dresden.—The Town Council of Dresden has requested Messrs. Siemens and Halske to submit a scheme for a central station. The station is to be built outside the town, as the authorities have not consented to relieve the town from the stringent regulations as to the erection of boilers.

Football.—Notts National Telephonic *v.* Sheffield National Telephonic.—Teams representing these towns met on Saturday last at Nottingham. A violent downpour of rain brought the match to a premature conclusion, ten minutes yet remaining to play, leaving Notts with a score of four to Sheffield none. On the 22nd inst. Notts pay the return visit.

Selby.—At the last meeting of the Selby Local Board of Health a resolution was passed that the Clerk should communicate with some electric lighting company, and ascertain the cost of providing the electric light in all public thoroughfares and in all public and private buildings now lighted by the Selby Gas Company within the district of the Selby Local Board.

The Verity Cricket and Football Club.—The Cricket and Football Club in connection with the firm of Messrs. B. Verity and Sons, of Covent Garden, on Friday evening gave their third annual smoking concert at the "Horseshoe"; Mr. J. B. Verity being in the chair. There were between two and three hundred persons present, and the meeting was an unqualified success.

Eastern Extension, Australasia and China Telegraph Company (Limited).—Particulars are given on page xv. of advertisements of the drawing of 125 bonds of £100 each of the Five per Cent. Debentures (1880 issue) of this Company. These debentures will be paid off at par on the 1st day of May next, at the Consolidated Bank, 52, Threadneedle-street, E.C., after which date interest on them will cease.

Royal Institution.—The following are some of the lectures arranged for after Easter:—Prof. C. V. Boys, three lectures on "The Heat of the Moon and Stars"; Prof. Dewar, six lectures on "Flame and Explosives"; Captain Abney, three lectures on "Colour and its Chemical Action." The Friday evening meetings will be resumed on April 18th, when a discourse will be given by Sir Frederick Bramwell, Bart., on "Electric Welding."

Reading.—At the last meeting of the Town Council, the Special Committee recommended that the Council should give consent to an application to the Board of Trade by the Laing, Wharton, and Down Construction Syndicate (Limited) for a licence to supply electricity for lighting purposes within the borough, subject to the terms and conditions of the licence being approved by the Council. The report was agreed to.

Damage by Lightning.—The *Journal Télégraphiste de Berne* of February 25th publishes a list of the cases of damage done by lightning to telegraph and telephone wires during 1888. In France 647 poles were struck, 347 being afterwards useless. In Germany 787 poles were struck, but only 266 were so badly damaged as to necessitate their renewal. In Germany 94 insulators were injured during the year, while in France the number reached 812.

Folkestone.—At the last meeting of the Corporation there was a debate on the subject of the electric light. The contract with Messrs. Crompton and Co. binds them to complete the arrangements for lighting the west end of the town by July next. Messrs. Crompton and Co. have applied for an extension of time for six months. It was decided that the application should be refused, and that the firm should be held to the terms of the contract.

Leamington.—At the last meeting of the Town Council the Mayor and Aldermen Wackrill and Gilbert presented a voluminous report on the inquiries they had made as to the working of the electric light in London. The deputation recommended that the Council should apply for a Provisional Order to enable them either to carry out works of their own or to license a company with whom they would be able to arrange suitable terms. The report was adopted.

Municipal Authorities and Electric Lighting Orders.—The annual meeting of the Association of Municipal Corporations took place on Wednesday last at the Guildhall, and was largely attended. The Town Clerk of Hull moved: "That the President of the Board of Trade be asked to receive a deputation from this Association upon the subject of electric lighting powers as affecting local authorities." The Town Clerk of Manchester seconded the motion, which was carried.

Smokeless Fuel for Generating Steam.—We notice by the Patent Records that a provisional patent has been granted to Mr. Arthur Shippey, for "Improvements in Compound Fuel for Preventing Smoke and Methods adopted for obtaining an Incandescent Fuel for Generating Steam and the Production of Heat." If Mr. Shippey succeeds in placing on the market a really smokeless fuel, it will, no doubt, lead to an increase in the number of small central lighting stations built in populous districts.

Edinburgh Exhibition.—A meeting of the Executive Council of the Exhibition was held on Friday last. It was reported that it had been arranged that a Chemin de Fer Glissant would be on exhibition. A considerable number of further subscriptions to the guarantee fund were announced. The Council resolved to have an electric railway, the contract for which will be proceeded with at once, Mr. Bennett being entrusted with the arrangement as to the number of cars to be used and the trains.

The Electric Light in Factories.—At the meeting of the shareholders in Cassell and Co. (Limited), held on Tuesday, Mr. R. Turner, the chairman and managing director, observed that fair space and working convenience were long a cardinal principle with the old firm (Messrs. Cassell, Petter, and Galpin), and it was still held; and the directors now had in view the possibility of further improvement by the substitution of electricity for gas throughout the whole of the offices.

The Institution of Electrical Engineers.—The students of the Institution held a meeting last Friday at the Sanctuary, when Mr. H. Walker read a Paper on "Ship Lighting," Mr. W. M. Mordey occupying the chair. A short discussion followed, in which the Chairman, Messrs. Muir, Stephens, Poynton, Horn, and Cirlo took part. Mr. Walker having replied, a vote of thanks to the chairman terminated the proceedings. At the next meeting, to be held on the 21st inst., Mr. R. Wightman will read a Paper on "Constant-Current Regulators."

Central London Railway Bill.—At the last meeting of the London County Council Mr. Beachcroft moved, "That,

Digitized by Google

as no resolution had been come to by the Council to oppose the Central London Railway Bill on its merits, and as the object of the Bill, if successfully attained, will effect a great metropolitan improvement without a charge upon the rates, the opposition of the Council to such Bill be confined to the taking of needful steps to secure the special clauses required to protect the sewers and other works of the Council." This resolution was adopted.

Croydon.—A special meeting of the County Council was held on Monday evening to consider the expediency of consenting to the Provisional Orders promoted by the Croydon Electric Supply Company, the South of England House-to-House Electricity Company, and the Crystal Palace and District Electric Lighting Order. Councillor Miller explained that the Council had already decided that the Orders promoted by the Croydon Electric Supply Company and the South of England House-to-House Supply Company should not be agreed to, and moved that consent should be given to the last Order. The resolution was carried.

Newcastle.—The Newcastle and District Electric Company are now supplying 26 customers, the total number of lights being equal to about 2,000 10 candle-power lamps. In addition to this the Company are supplying the current for 500 lamps at Deuchar's Rooms, Barras Bridge, and by the end of this month or the beginning of next it is anticipated that fully 5,000 lamps will be connected to the mains. The Newcastle Electric Supply Company are very busy, and the difficulty they experience is not so much in getting contracts as in confining their operations to a given district. The light, wherever it has been introduced, is reported to have given every satisfaction.

Trial Trip of the Twin-Screw Cable Steamer "Relay."—On Saturday this fine steamer, particulars of which will be found in our issue of January 31st, had her official trial at sea for six consecutive hours. Everything worked satisfactorily. During the trial luncheon was served in the saloon, the following gentlemen being present :—Mr. J. E. Thompson (of the firm of Robert Thompson and Sons), Mr. J. R. France, Mr. H. Clark (representing George Clark, Limited, builders of engines), Captain Lugar (who will take command), Mr. Rosser (inspector for the owners for both ship and machinery), Mr. Watt (Board of Trade surveyor), Mr. Hildrey (chief draughtsman to the builders), Mr. Cay (outside manager to engine builders), and a large party of friends.

Edinburgh.—We cull the following from a long and interesting article on the present position of the electric lighting question in Edinburgh, which appeared in the *Scotsman* of March 6th :—"Granted in our own case, therefore, that the Board of Trade insert in the Provisional Orders they recommend for the confirmation of Parliament, sufficient clauses protecting all public interests in our street management, all our public works, and the safety of our persons, fixing a reasonable maximum charge for the commodity to prevent abuse or unrestricted monopoly in our city, and placing a right of superintendence and supervision of the supply in the hands of our Town Council, what more do we, as ratepayers and citizens, require if a good company be selected?" What more indeed!

Brighton.—At the last meeting of the Town Council a renewed attempt to obtain the immediate removal of Mr. Magnus Volk's electric railway was defeated. At the same meeting the proceedings of the Pavilion Committee were read. They contained the award of Mr. A. M. Channell, Q.C., in the disputes between the Corporation and Maxim-Weston Electric Company, in respect to the contract for reconstructing the electric lighting works at the Pavilion. It was found after going through the accounts there was due from the contractors to the Corporation £6. 5s. 10d. The contractors are to pay the costs of the award. The proceedings of the Lighting Committee recorded a refusal on the part of the Committee to consent to an interview with Mr. R. Hammond, of the Brighton and Hove Electric Lighting Company, and also that the offer of the Company to light the front at the same price as the Corporation were paying for gas, was declined.

Telephonic Development in the West of England.—The Western Counties and South Wales Telephone Company announce that they are prepared to open exchanges at Tavistock, Horrabridge, Yelverton, Gunnislake and Calstock. These places would be connected with Plymouth, and thus be placed in communication with Plympton, Ivybridge, Avonwick, Torquay, Totnes, Brixham, Buckfastleigh, Dartmouth, and Ashburton. A meeting to consider the matter was held at Tavistock Guildhall, on Wednesday last, and it is hoped that sufficient support will be forthcoming to justify the proposed extension of the telephone. A still further development is under consideration, and will be carried into effect during the year if the Company receives sufficient support. It is contemplated to erect trunk lines between Newton Abbot, Dawlish, Teignmouth, Exeter, Taunton, Bridgwater, Weston-super-Mare, and Bristol, connecting these towns with the already established system from Bristol to Bath, Cheltenham, Gloucester, Newport, Cardiff, the Rhondda and Ebbw Vale coal districts, Swansea and Llanelly.

The London County Council Subways and Overhead Wires Bill.—No fewer than thirty-six petitioners have, within the time limited by the Standing Orders, deposited petitions in the Private Bill Office of the House of Commons praying to be heard in opposition to the passing of the Bill promoted by the London County Council for constructing subways for pipes and wires under the streets of the metropolis, and for the creation of an efficient system of control over overhead wires and cables. Although this number of petitions is greater than any number that has yet been deposited against any English Bill now before Parliament, it does not fully represent the strength of the opposition which this Bill will have to encounter, inasmuch as the London Water Companies and a large majority of the Electric Light Companies have consolidated their oppositions and are represented by only two out of the thirty-six petitions lodged against the Bill. An analysis of the petitions shows that among the opponents are thirteen railway companies, ten local and other governing authorities, five gas companies, and six telephone, hydraulic and other companies.

The Board of Trade on Electric Lighting Bills and Orders of 1890.—The Board of Trade Report on Electric Lighting and other Bills has been published, and according to it there are eight Electric Lighting Bills in England and Scotland, with a combined proposed capital of £70,000, of which £20,000 relates to English, and £50,000 to Scotch Bills. The applications for Provisional Orders for Electric Lighting amount to 161, with a proposed estimated capital of £9,242,828, of which English companies absorb £7,908,000, Scotch £1,131,000, and Irish £203,000. Of the English companies the largest in point of capital (£300,000) is that of the Westminster Electric Supply Corporation, seeking to supply electricity for public and private purposes in the parishes of Paddington and St. Marylebone; the smallest is that of the Electric Trust in Bognor, which proposes to supply electricity within the Local Board district of Bognor, with a capital of £4,000. In Scotland, Aberdeen proposes to have two installations, one by the Town Council and one by the Scottish House-to-House Electricity Company; while in Ireland Provisional Orders are applied for in Belfast, Cork, Londonderry, and Galway.

St. Pancras Vestry.—At the last meeting of this Vestry the Dual Committee of the Parliamentary and General Purposes and the Lighting Committees presented a report upon the action taken by them respecting electric lighting. In the first place they gave up all idea of taking the premises in Edward-street, held by the Vestry for a short lease, and also a site in the King's-road, as both were considered unsuitable. It was thought by the Committee that it would be most desirable to obtain a freehold; and they had found an estate in Stanhope-street of 22 houses, for which one of the electric lighting companies had offered £13,000, but had not completed owing to the action of the Vestry in refusing to have private companies to compete. The site contained 20,600 superficial feet, and could be had for £10,000; while Edward-street, with only 12,000ft. area, would cost £15,000. Without pulling all the houses down they would have sufficient room with half, so there would be an income from ten houses of about £300 a year; this in forty years would pay the principal and interest without costing the ratepayers one halfpenny, and at the end of that period the parish would be the possessor of this estate that had cost them nothing.

MAGNETISM IN IRON AND OTHER METALS.*—IX.

BY PROF. J. A. EWING, F.R.S.

(*Continued from page 442.*)

§ 46. **Magnetisation Curve.**—A convenient way of representing such results graphically is to draw a curve showing the relation of the magnetising force to I or to B. In Fig. 20 a curve showing the relation of the magnetising force of the solenoid to I is drawn from the above table. O A B is the ascending limb got by applying a magnetising current, the iron being originally in a non-magnetised and perfectly neutral state. From B to C the magnetising current is being reduced to zero from C to D an increasing negative current is being applied

This example is thoroughly characteristic of the behaviour of annealed wrought iron. The ascending limb of the curve may be divided, broadly, into three portions. In the first, under feeble magnetic forces, the gradient of the curve is very small, which means that at this stage there is (comparatively) very little magnetic susceptibility.† Later, as the force increases, the curve becomes exceedingly steep, and nearly straight; this is the region of great susceptibility. Then, lastly, the curve rounds off until the rate of ascent again becomes small, so that the susceptibility diminishes, and any considerable addition to I can then be brought about only by applying a very strong magnetising force.

This third stage is a necessary consequence of the well-known phenomenon of magnetic "saturation." We shall see later that the value of I has a definite limit which cannot be exceeded no matter how high the magnetic force be raised.

§ 47. **Residual Magnetism and Coercive Force.**—In the descending limb of the curve it is interesting to notice how little of the magnetism disappears as the magnetic force is withdrawn. Even when the solenoid current is reduced to zero, the residual magnetism O C is in this case 1,162 C.-G.-S. units, which is no less than 92 per cent. of the value reached when the current was on (1,262 units). This residual magnetism is, however, very feebly held. Applying a reverse magnetic force quickly removes it, as the continuation C D of the descending limb shows, and a force, O D, of − 2·75 C.-G.-S. units suffices to destroy it altogether. This force O D may be said to measure the degree of stability with which the residual magnetism is held, and accordingly Dr. Hopkinson calls it the "coercive force," thus giving an exact and very useful meaning to an old loosely applied term.

§ 48. **Correction of the foregoing results to allow for the reaction of the Specimen on the Magnetising Field.**—When the specimen is so long as it was in this instance (400 diameters), its ends have no great influence on the field, and we might without any serious error ignore the difference between H′ and H, and take the magnetising force of the solenoid to represent the whole magnetic force. The approximate allowance for the effect of the ends may, however, be made by treating the specimen as an ellipsoid.* By § 33 we have, in that case,

$$H = H' - 0{\cdot}00045\ I.$$

Thus, for instance, the magnetic force producing a magnetisation of 1,000 is, on this basis, 0·45 units less than the force due to the solenoid, and for other values of I a proportional correction is to be made. We may therefore allow for this in the diagram† (Fig. 20) by drawing a straight line, O E, from O to cut the line of I = 1,000 at a force of 0·45. Then the true value of H for any point in the curve of magnetisation is to be measured from this line, instead of from the line O C. In other words, the effect of the ends of the specimen is to *shear* the diagram in the direction in which H is drawn, through the angle C O E; and we may deduce the corrected curve from the original curve O A B by setting each point, such as A, back through a distance A A^1 equal to the distance between O E and the axis O C for the corresponding value of I. The same construction obviously applies to the descending limb. The dotted curves O A^1 B and B C^1 D have been drawn in this way, and they may be accepted as giving a more nearly correct representation of the relation of I to H than is given by the original curves.

One effect of the change is to make the susceptibility greater: its maximum value (which is found by drawing a tangent from O to the curve) rises from 189 to 209. Another effect is

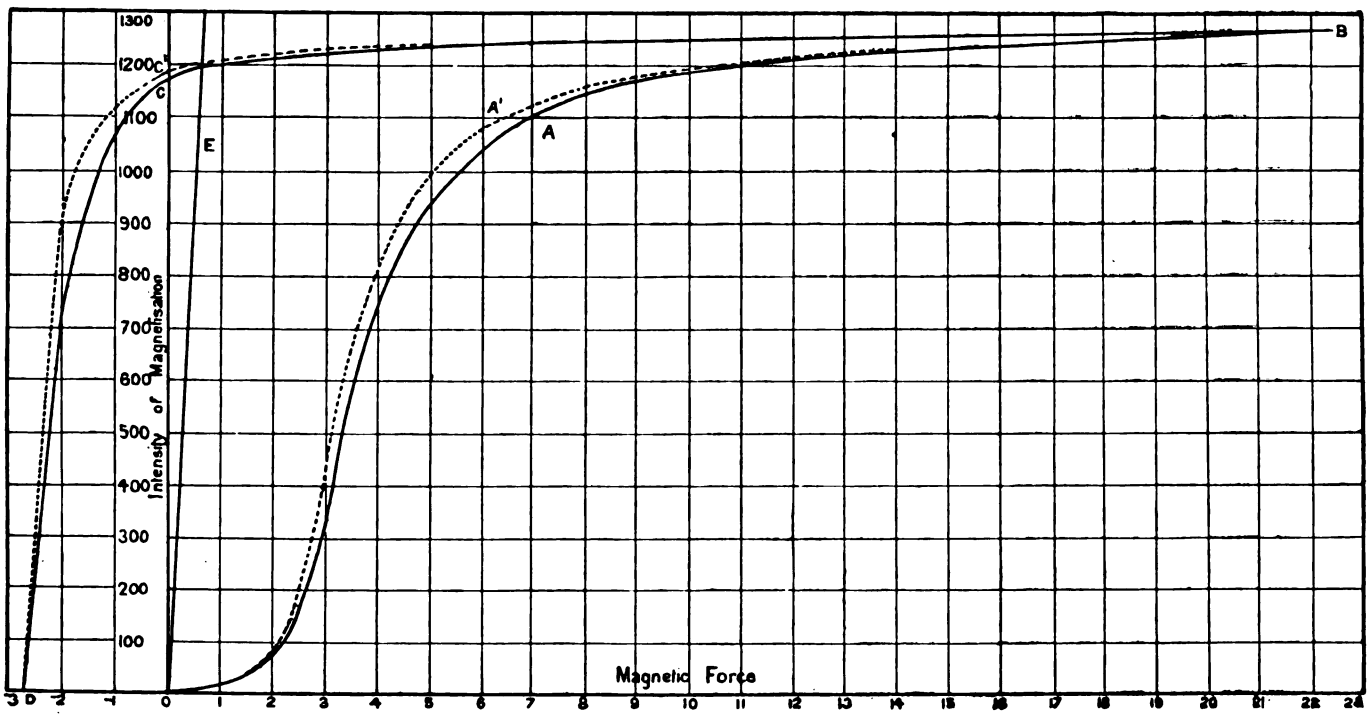

FIG. 20.—Curve of Magnetisation in Annealed Wrought Iron.

* All rights are reserved.

† The comparatively small susceptibility of iron to feeble forces seems to have been first clearly pointed out by Stoletow (*Phil. Mag.*, Vol. XLV., 1873, p. 40), whose observations on the relation of magnetisation to magnetic force were confirmed and greatly extended by Rowland (*Phil. Mag.*, Vol. XLVI., 1873, p. 140; and Vol. XLVIII., 1874, p. 321).

* Probably this correction is rather excessive. In a cylindrical rod the magnetism is more nearly concentrated at the ends than in an ellipsoid. Its effect on the magnetic force is unequal at different parts of the length, but its mean effect may be expected to be less than in the case of an ellipsoid.

† This construction is used by Lord Rayleigh in a Paper on "The Energy of Magnetised Iron" (*Phil. Mag.*, Vol. XXII., 1886, p. 175.)

Digitized by Google

to increase the residual magnetism, making it 93·8 per cent. of the induced magnetism instead of 92·1 per cent. Another effect is to increase the steepness of the gradient in the steep part both of the ascending and of the descending limb.

Table II. gives the results of the same experiment (for the ascending process) on the supposition that the correction of H to be made on account of the ends of the specimen does not sensibly differ from the correction which would have to be made in an ellipsoid 400 (equatorial) diameters long. Values of B, μ and κ are given as well as I and H. B, which is $4\pi I + H$, is so nearly equal to $4\pi I$ that we might adapt the curve of Fig. 20 to exhibit the relation of B, instead of I, to H, by simply altering the scale of the ordinates, so that 100 of I should represent 1,257 of B.

TABLE II.

H	I	$\kappa = \frac{I}{H}$	B	$\mu = \frac{B}{H}$
0	0	—	0	—
0·32	3	9	40	120
0·84	13	15	170	200
1·37	33	24	420	310
2·14	93	43	1,170	550
2·67	295	110	3,710	1,390
3·24	581	179	7,300	2,250
3·89	793	204	9,970	2,560
4·50	926	206	11,640	2,590
5·17	1,009	195	12,680	2,450
6·20	1,086	175	13,640	2,200
7·94	1,155	145	14,510	1,830
9·79	1,192	122	14,980	1,530
11·57	1,212	105	15,230	1,320
15·06	1,238	82	15,570	1,030
19·76	1,255	64	15,780	800
21·70	1,262	58	15,870	730

§ 49. **Differential Susceptibility and Differential Permeability.** In many cases we are less concerned to know the actual ratio of I or of B to H than to know the rate at which I or B is increasing or diminishing with respect to H—in other words, the gradient of the magnetisation curve. We have seen that the gradient $\frac{dI}{dH}$ begins by being small, then becomes very large, and then again becomes small as the region of saturation is approached. Prof. Knott has proposed to call this quantity the "differential susceptibility"; similarly $\frac{dB}{dH}$ may be called the differential permeability. In the example which has been quoted, the differential susceptibility (after applying the ellipsoidal correction) has a maximum value in the ascending limb of 530, which is sensibly constant, while I changes from, say, 150 to 650. The corresponding differential permeability is 6,660. In the descending limb the greatest differential susceptibility is 1,660, and this is sensibly constant, while I changes for 700 to 0 (and to − 700, as we shall later see in other examples). The corresponding differential permeability is 20,850.

(To be continued.)

REVIEWS.

"Practical Notes for Electrical Students." Vol. I. By A. E. KENNELLY and H. D. WILKINSON. [THE ELECTRICIAN Printing and Publishing Company (Limited).]

This book is mainly a reprint of the excellent series of articles entitled "Letters for Learners and Unprofessional Readers," which were commenced in *The Electrician* towards the close of the year 1887. It is designed, as the title of those articles implies, chiefly for those who are but slightly grounded in electrical matters, and with this view the authors have endeavoured to render their language as simple as possible, and to exclude all mathematical expressions. In this attempt the authors have succeeded very well, and the practical nature of the matter will render it of service to many readers beside those for whom the book is professedly written.

The work is divided into nine chapters, whose unequal length is due, partly to the fact that the matter was originally written as serial articles for the press, and partly because these were commenced by one of the writers and finished by the other. The introductory chapter is well designed to impart correct notions of the fundamental principles underlying electrical measurements. The elementary definitions are referred directly to energy considerations, the importance of which is the first thing pointed out. Thus the quantity of electricity produced by a voltaic cell is connected with the quantity of electrode consumed, and the electromotive force of the cell with the energy developed chemically by the consumption of the unit quantity of the electrode. The second chapter treats critically of the various kinds of batteries used in practice. The Latimer Clark standard cell is mentioned, but its E.M.F. is stated incorrectly, and its high-temperature coefficient is not given at all. The internal resistance of this cell is generally supposed to be immaterial, owing to the belief that no appreciable current should be taken from it. Prof. Threlfall has, however, found that the constancy of the E.M.F. may be relied on when the internal resistance is small, even if moderate currents are sent by the cell. The third chapter is devoted to electromotive force and potential. Graphical processes are freely used to illustrate the distribution of potential in various combinations of batteries. The following chapter on resistance exemplifies an excellent characteristic of the book, the subject matter of which is constantly being rendered clear by means of numerical examples fully worked out. The authors, instead of using symbols in their mathematical expressions, have, wherever possible, used the actual numbers taken from a typical example. The expressions so obtained serve the same purpose as formulæ, and, no doubt, seem simpler to many. Sir William Thomson's convenient, but very ugly word *mho* is introduced to represent the unit of conductivity, and the laws of parallel resistances are thereby rendered very simple. As, however, the qualities of a circuit are in practice defined by its resistance in ohms, not by its conductivity in *mhos*, too much prominence is given to the latter quantity. This is more especially the case because Ohm's law is not mentioned till the next chapter, and even then the law is stated more as a definition of resistance than as an experimental fact. It is purely an experimental matter to show that the ratio of the difference of potential required to make electricity flow through a conductor to the strength of the current produced is a constant for the same conductor whatever potentials and currents are employed. That this ratio, which is called the resistance of the conductor, is a constant, and corresponds to some physical property of the wire independent of current, is the really vital part of Ohm's law. It is not enough to state, as the authors do, that the current in amperes is obtained by multiplying the E.M.F. in volts by the conductivity in *mhos*, or, as is more usual, by dividing the E.M.F. so expressed by the resistance in ohms.

The properties of electric currents are illustrated by reference to the closed circuit system of telegraphic signalling and to the phenomena of retardation in connection with submarine cables. The next chapter, dealing with the subject of current indicators, is important. Many practical forms suitable for use with various kinds of work are described and illustrated by numerous engravings. The winding of the bobbins and the methods for supporting the indicating needle are discussed in detail. The best resistance to wind the instrument for any given purpose is determined by a simple graphical process, thus avoiding the need of any symbolic calculation. The seventh and eighth chapters are of a very practical nature, full of useful hints and such as to quite justify the title of the book. The uses of indicators in testing for continuity, detecting faults, testing for identity of stranded wires, determining insulation resistances, &c., are clearly brought out. Various forms of insulators are illustrated, and full directions for making insulation tests are given. The seventh chapter concludes with a very complete description of the General Post Office standard indicator. The subjects next treated are the calibration of current indicators, the use of calibration curves, the functions of shunts, and calculations connected with them.

Digitized by Google

The concluding chapter, which is longer than the rest of the book put together, deals with magnetic fields and their measurement. Free use is made of iron filing figures to explain the phenomena of lines of force. The fact that these figures only indicate the lines of force outside the iron, and that consequently they fail to exhibit the closed ring character of the lines, might with advantage have been definitely stated here. The continuous nature of the lines is, however, brought out clearly later on in the book. The different magnetic units are defined and discussed, their mutual relations being clearly brought out by means of numerical examples. The mechanical principles necessary to understand in connection with the reactions of magnets and magnetic fields are explained. The magnetometer method of comparing magnets is next discussed. Very simple forms of the instrument are described, and the various parts are illustrated by engravings, so that the reader may easily, if he chooses, make the apparatus and carry out the experiments for himself. The molecular nature of magnetism is vividly shown by an account of Prof. Hughes' interesting researches. The second section of the chapter treats of electromagnetic fields. The numerous uses of electromagnets in telegraphy are described, and an explanation is given of the device for diminishing the time constant of electromagnets by winding the two magnetising coils in parallel. The influence of iron cores and the properties of magnetic circuits are very completely shown by means of a good series of experiments made by Mr. Wilkinson. The inductive properties of iron, and the short-circuiting effect on the lines of force produced by putting an armature across the poles of an electromagnet, are clearly brought out. The subjects of permeability and susceptibility are described in simple language, and made clear by a detailed account of many series of experiments made by one of the authors, and also by a summary of the classical researches of Ewing. The book concludes with a discussion of the nature of the magnetic fields of coils and solenoids.

The book is throughout very fully illustrated by excellent engravings, and the authors may be heartily congratulated on their success in describing in a simple, thorough, and practical way the matter they have dealt with. W. E. S.

TELEPHONIC SPECIFIC INDUCTIVE CAPACITY.*

BY F. H. SAFFORD AND G. U. G. HOLMAN.

In a Paper on the "Construction of Telephone Circuits," read before this Academy on June 15, 1887, by the electrician of the American Bell Telephone Company, Dr. Jaques, it was pointed out that the readiness with which telephonic conversation may be carried on over any circuit, whether made up of cables or pole lines, or both, depends :—

"1. On the total electrical resistance of the circuit joining together the two stations.

"2. On the electrostatic capacity of this circuit."

And the general rule was laid down :—

"No matter what may be the distance between two points, good business conversation may be carried on between them, provided they be connected by a pole line or cable, or both, the product of whose total resistance by its total capacity is less than 2,000 if transmitters of the Blake type be used, and less than 4,500 if transmitters of the Hunnings type be used."

It is evident, therefore, that in the construction of a telephone line it is desirable to reduce both the *resistance* and the *capacity* to a minimum. In a pole line, since the wire is suspended high above the earth, the capacity is always small, and the resistance is the factor that we must try to keep down. In cable lines, however, the capacity becomes a factor to be respected. In lines made up, as is most generally the case, of a comparatively short section of cable and a larger section of iron pole wire, the capacity of the cable becomes pre-eminently the factor to be respected ; for, since the limit of conversation is here determined by the product of the capacity of the cable and the resistance of the whole line, a small percentage of saving in the capacity of the cable gives an enormous gain in the readiness with which conversation may be carried on over the line. It becomes of vital importance, therefore, to choose an insulating material for telephone cables of low specific inductive capacity.

* Paper read before the American Academy of Arts and Sciences.

We have accordingly measured the electrostatic capacity of a considerable number of substances used for insulating wires in cables, and, since the specific inductive capacity for the same insulator is very different for telephone currents from what it is for telegraph currents, because the charge and discharge take place so much more frequently, we have adopted a method and apparatus in which currents of telephonic frequency are used. This apparatus is a Gordon induction balance, in which the substances were charged and discharged by currents from an induction coil, and the balance was observed with a telephone instead of an electrometer.

With this apparatus, we measured the specific inductive capacity of a considerable number of insulating materials, and each when subjected to various rates of charge. We found that the capacity varied very materially with the rate of charge, some substances increasing and others decreasing ; but no general rule was evolved. We found that measurements of the capacities of telephone cables made by the ordinary galvanometric measurements gave no indications of the comparative merits of these cables for telephonic work. Finally, we made an accurate series of measurements of the specific inductive capacity of the following substances, when submitted to actual telephone currents. The values might perhaps be called the "telephonic specific inductive capacity," leaving the expression "telegraphic specific inductive capacity" to indicate values measured in the old-fashioned way.

TABLE OF SPECIFIC INDUCTIVE CAPACITIES, MEASURED BY TELEPHONE CURRENTS.

Petroleum (Brooks cable)	1·6
Solid paraffin	2·0
Cotton saturated with paraffin in vacuum (Faraday cable)	2·0
Cotton boiled in paraffin (Patterson cable)	2·6
Indiarubber	3·7
Artificial gutta percha (Gwynn)	3·9
Gutta percha	4·2
Glass	4·6
Water	6·3

An inspection of this table shows that, so far as capacity is concerned, petroleum is the best substance to be used, and doubtless this would be the case were it possible to keep it free from water ; but water, we see from the table, has a specific inductive capacity of 6 3, so that its presence in the petroleum raises the capacity from the lowest to the highest in the list. This observation is borne out by actual experience with "Brooks" cables in telephony. When new, and the petrolum dry, it works excellently ; but as water finds its way in, the cable rapidly loses its efficiency for telephonic work. This action of the water is quite different from its action as a *conductor* to produce leakage ; for the loss of electricity due to leakage in a "Brooks" cable that has lost its efficiency from the presence of moisture is entirely insufficient to account for the deterioration.

Next to petroleum, solid paraffin is seen to be the best substance to use ; but on account of mechanical difficulties it has never been found practicable to coat wires directly with solid paraffin. If the wires are wound with cotton and then boiled in paraffin, as they are in making "Patterson" cables, the specific inductive capacity is raised to 2·6, an increase of 30 per cent., which we have seen is a very great detriment. If, however, the wires are wound with cotton, and the air and moisture removed by the aid of heat and a vacuum, and they are then boiled in paraffin, from which the air and moisture have also been removed by heat and vacuum, the specific inductive capacity again falls to 2·0, which is the same as that of solid paraffin. This process is used in preparing the "Faraday" cable. It is possible that the inferiority of the "Patterson" cable as compared with the "Faraday" is due largely to the moisture retained in the cotton, which we have seen has a capacity of 6·3.

Leaving the paraffin cables, rubber is the next best, then gutta-percha, and poorest of all is glass ; but all of these substances have so high a specific inductive capacity as to entirely unfit them for telephonic work.

CONTINUOUS OUTPUTS OF TWO-POLE DYNAMOS AND MOTORS.

BY ALBION T. SNELL.

The following equations are intended for the use of engineers in charge of electrical plant, and demand no special electrical knowledge, the measurement being made by a foot-rule. They give approximately the safe average output of dynamos and motors *for continuous running*, and are based on observations made during the past few years with machines of nearly all the best manufacturers. They, of course, only average the results, and so will not

Digitized by Google

give a sufficiently high output for machines of abnormal proportions, *i.e.*, with unusually heavy fields, or very deep armature cores. With very light machines the formulæ will give results too high.

With normal machines the outputs given by these equations will generally be about 10 per cent. lower than that given in the price lists. This margin is made to meet the contingencies incidental to continuous running.

The outputs are expressed in terms of the armature lengths and diameters and the numbers of revolutions per minute. The constants are carefully determined from a large number of tests. (They depend on the fact that the average magnetic induction through an armature is determined by the effective area of the iron and the magnetic density per unit area. For a given field excitation the total induction will be sensibly constant through considerable variations of radial depth of armature. This is apparent when we consider that the conductivity of the armature iron bears but a small proportion to the conductivity of the magnetic circuit as a whole, and hence an increase of iron will not largely increase the total induction, but will almost always decrease the induction per unit area.) The outputs of dynamos are given in watts (746=1 horse-power). Those of motors are given in brake-horse-power. The linear measurements of the armatures are made in inches. l=the length of the armature parallel to the shaft. In the case of cylinders the length may be taken over all, *i.e.*, from one end of the winding to the other. In drums, only that part of the armature covered by the pole-pieces must be measured for the value of l. The outer diameter d of the armature is measured over the windings. The revolutions per minute can be taken by a speed indicator or counter.

For two-pole dynamos:

l=length of armature in inches.

d=diameter of armature in inches.

r=number of revolutions per minute.

Drum armature: $l\,d^2\,r\,\cdot 015$=output in watts . (I.)

Cylinder armature: $l\,d^2\,r\,\cdot 01$=output in watts . (II.)

For two-pole motors: (Symbols have the same signification.)

Drum armature: $l\,d^2\,r\,\cdot 000015$=B.H.P. . . . (III.)

Cylinder armature: $l\,d^2\,r\,\cdot 00001$=B.H.P. . . . (IV.)

With a four-pole machine, since for the same magnetic density in the armature double the field excitation required for a two-pole machine is necessary, the *constant* must be multiplied by *two*. Some four-pole machines, however, have very light fields, and then the output is given nearly correctly by the formulæ. Generally, with machines of more than two poles the equations will only be useful for determining the safe load for a *first run*. If the heating be very little the output can then be gradually increased until a suitable load be obtained.

The following examples, chosen at random, show the method of applying the formulæ to various machines:—

Edison-Hopkinson Dynamo.—Drum armature, 9¾in. in length, 10in. in diameter, 970 revolutions per minute.

Equation (I.)

$$9{\cdot}75 \times 10^2 \times 970 \times {\cdot}015 = 14{,}200 \text{ watts.}$$

The output is given at 15,700 watts.

Paterson and Cooper Dynamo.—Cylinder armature, 10in. in length, 13·5in in diameter, 850 revolutions per minute.

Equation (II.)

$$10 \times 13{\cdot}5^2 \times 850 \times {\cdot}01 = 15{,}500 \text{ watts.}$$

The actual output is given at 16,200 watts.

Immisch Motor.—Drum armature, 14in. in length, 7·25in. in diameter, 1,000 revolutions per minute.

Equation (III.)

$$14 \times 7{\cdot}25^2 \times 1000 \times {\cdot}000015 = 11 \text{ B.H.P.}$$

This machine is actually designed to give 10 B.H.P.

Immisch Motor.—Cylinder armature, 16in. in length, 24·5in. in diameter, 450 revolutions per minute.

Equation (IV.)

$$16 \times 24{\cdot}5^2 \times 450 \times {\cdot}00001 = 43{\cdot}2 \text{ B.H.P.}$$

The actual horse-power given continuously by this motor is between44 and 45.

The writer has found these equations of great assistance in selecting the size of armature for a given machine, before making more complete calculations.

CARBON TESTS.*

BY E. F. PECK.

The first electric light of any consequence was used by Sir Humphry Davy in 1810. He had discovered that when the two terminals of a charged electric circuit were separated a short distance, an electric spark would pass between these terminals by evaporising the material of which the electrodes were composed, and that the vapour thus produced would continue to carry the current between the electrodes, and that these vapours, together with the highly incandescent solid ends of the electrodes, would emit a powerful light. The vaporised material bridging the space between the terminals of the electric circuit he denominated the electric arc, for the reason that these vapours would pass in a curved path between the two electrodes. Sir Humphry Davy demonstrated this interesting phenomenon by using a great variety of material for the electrodes; and he found that the most brilliant effects were produced when the electrodes were made of carbons. The carbon used by him was charcoal made from various woods. It was found, however, that the charcoal, from whatever wood it was made, always had a considerable electrical resistance, and was so rapidly consumed that it could not be used for the production of arc lights for practical purposes, such as general illumination.

Other electricians took hold of Sir Humphry Davy's discovery, and their efforts were directed towards the discovery of materials for the production of electrodes of greater durability and better conductivity. It was finally discovered that carbon deposited in the neck of gas retorts possessed a higher degree of conductivity and was exceedingly hard, and therefore would be very durable when used as electrodes for arc lights. Rods or pencils of this gas-retort carbon were made and shaped at great expense and trouble, and they were found to be excellent substitutes for the charcoal electrodes. Still these gas-retort carbons could never be used on a large scale, for the reason that they could be shaped to the required form only at a very great expense, being exceedingly hard. The next step in the improvement of carbon electrodes for arc lamps was made in 1842, when Bunsen invented what he called the "plastic" carbon as the negative electrode of his battery. This carbon electrode was made of various mixtures of powdered charcoal, molasses, &c. It could be shaped to any desired form, and was made by Bunsen in the shape of hollow cylinders and flat plates. When it was found that this carbon electrode could be used to advantage for the production of electric arc lights, it was at once substituted for the gas carbon. This substitution was not a universal one; for as late as 1873 and 1874 Prof. Tyndall was in the habit of using gas-retort carbons in the production of electric arc lights, although he complained bitterly to his audiences that the production of his carbon electrodes involved great expense and trouble. The carbons burned at the Centennial Exposition in 1876 were of this material, but we have no data of their life or resistance. They were made by Carré of France, and the current was from a Gramme machine.

From 1842, when Bunsen invented his "plastic," or moulded carbon, to 1879, many inventors of this country and Europe tried to improve on his discovery. Their chief object was to produce a carbon of greater and more uniform density, and of higher conductivity. The English patents were especially numerous during this period, and their mixture in the more enlightened state of the art seems very ludicrous. Though some laboured at the problem nearly fifteen years, on the whole no great improvement was made. This poverty of result was largely due to the fact that the dynamo apparatus of to-day was unknown. All arc lights were produced by currents generated by batteries. The modern arc lamp, with its simple but effective mechanism, was unknown. The arc light was only a curious laboratory plaything, generated expensively and burned disadvantageously. The proper experimental condition to enable an inventor to produce good carbons did not exist, and the financial stimulus of commercial demands was wholly absent.

The modern arc light carbon of commerce is hardly ten years old. It became a necessity as soon as the modern dynamo apparatus was completed, and commercial lighting by electricity was seen to be coming in the near future. The problem may be said to have been undertaken in 1878. The first point was to discover crude carbon that was both pure and cheap. At the suggestion of Mr. Fayette Brown, of Cleveland, Ohio, his son, Mr. A. E. Brown, then experimenting for the Brush Electric Company, tried residue from petroleum. Careful experiment proved this to be the long-sought-for crude material, nor have the investigations of the past ten years found any better. The next point was to manufacture carbons of the requisite quality. Nearly three years later the Brush carbon was produced. The first cost of these was very high and the demand small. Where carbons are now sold by the

* Read before the National Electric Light Association, Kansas City, February, 1890.

Digitized by Google

hundred thousand, they were then sold by the dozen. Like most new articles, the process of manufacture was roundabout and tedious; consequently, both the cost and market price of carbons ten years ago was very high, the first carbons selling as high as $125 per 1,000. I cannot learn that any tests were made of these carbons for resistance, brilliancy, or even exact life. In those days manufacturers were well satisfied if they could make carbons that would burn fairly well, and gave other considerations very little thought, because they were relatively very unimportant.

Besides Mr. Brush and his associates, there were several others in different parts of the country working at the carbon business on different lines. At Ansonia, Conn., the Messrs. Wallace were experimenting with forced carbons, with much success, following the process of Carré of France. This carbon was very dense and hard, and when sounded gave forth a ring almost like a bell. Not to mention many others, Mr. Thompson of Newark, N.J., was also in the field; but, clinging to gas-retort carbons for his crude material, did not meet with the success achieved by his competitors. Since those early days of experimental work, manufacturers have paid especial attention to reducing the cost, lowering the resistance, and increasing the brilliancy and life of the carbon.

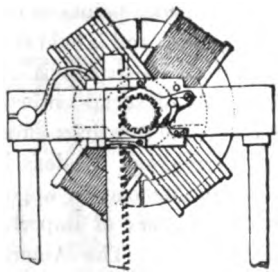
Early in the spring of 1889, at the suggestion of a representative of one of the large carbon manufacturers, I decided to base a year's contract for carbons on the comparative test of the best-known carbons in the market. I made two or three tests, taking into consideration simply the life and resistance of the carbons as adapted to the system of lighting we were using. The tests were rather crude and not made for the purpose of booming any particular carbon, but to satisfy myself as to what carbon I could best afford to burn. The final test was made with a group of Thomson-Houston lamps on a 6½ ampere circuit. Two sets of carbons of each make were placed in the lamps, and each lamp adjusted to the lowest point a quiet arc could be be maintained. A record was made of the time of starting each lamp, and they were then allowed to burn until all the lamps had cut themselves out automatically, by the burning out of the carbons. The electromotive force at the terminals of each lamp was then recorded at intervals of half an hour through the day. The result of the test, stated briefly, was as follows:—

	Nos.	Nos.	Nos.	Nos.	Nos.	Nos.
Lamps.	1 & 2.	3 & 4.	5 & 6.	7 & 8.	9 & 10.	11 & 12.
Average E.M.F.	42·23 ...	42·73 ...	47·16 ...	48·37 ...	47·76 ...	49·66
Average inches burned per hour	1·23 ...	1·46 ...	1·44 ...	1·57 ...	1·72 ...	1·69

As will be seen by this table, there was a difference of 7·43 volts, or a saving of about 15 per cent., in the E.M.F. of the best over the poorest carbon tested, and a difference in life of ·49in. per hour, or a saving of 29 per cent. In a station burning a thousand arc lamps, this means a saving of 64·73 electrical horse-power, without considering the saving in carbons. The figures given above show very plainly the importance of such tests, and I would recommend that superintendents and managers of central lighting stations give this matter their consideration before adopting any special make of carbons.

THE SCHNEIDER ARC LAMP.*

The mechanism of the Schneider arc lamp consists of a toothed rack gearing into a ratchet wheel. Upon the axis of this latter are mounted two coils, one of which is traversed by the main and the other by the shunt current. These coils actuate two semi-circular



cores, arranged with their similar poles opposite one another. The relative influence of the two coils is altered by the variations in the length of the arc: this causes the armatures to rotate and restore the proper distance between the carbons.

* Translated from M. Hippolyte Fontaine's "Éclairage à l'Électricité," by kind permission of the author.

THE CONDUCTIVITY OF VACUUM.*

Dr. James Moser, of the Physical Laboratory of the Imperial University of Vienna, brought the following interesting facts before a recent meeting of the Imperial Academy of Sciences. A Geissler tube was enclosed in another glass tube connected to a mercury pump and placed near to a powerful induction coil serving as a source of electrical oscillations, when the following effects were noticed:—1. When the outer tube was at atmospheric pressure, the inner tube was light blue, and the outer one unaffected. 2. This appearance was reversed as soon as the air in the outer tube was sufficiently exhausted; then the inner tube was dark, the outer one becoming conducting and exhibiting a reddish glow.

The question remained, what would happen if the air in the outer tube were still further exhausted? It is known that the discharge of Geissler tubes with electrodes is diminished at a very high vacuum. The cause of this diminution has been much discussed. Some hold the cause to be the non-conductivity of the vacuum; others attribute it to surface resistance at the electrodes. This experiment makes it easy to decide between these two theories, for there can be no question of electrode resistance, as there are no electrodes. The exhaustion was therefore carried still farther. The outer tube then again became non-luminous and the inner one glowed as at first. Thus it was shown that the more complete vacuum has no screening effect, and loses its conducting power.

MEETINGS OF SCIENTIFIC SOCIETIES, &c.

(To-night) FRIDAY, March 14th.

ROYAL INSTITUTION.

9 p.m. Evening Discourse: "The Glow of Phosphorus." By Prof. T. E. THORPE, F.R.S.

SATURDAY, March 15th.

ROYAL INSTITUTION.

3 p.m. Afternoon Lecture: "Electricity and Magnetism." By the Right Hon. Lord RAYLEIGH, F.R.S.

SOCIETY OF ARTS.

3 p.m. Popular Lecture II.: "The Atmosphere." By Prof. VIVIAN LEWES.

MONDAY, March 17th.

SOCIETY OF ARTS.

8 p.m. CANTOR LECTURE IV. 1: "Some Considerations concerning Colour and Colouring." By Prof. A. H. CHURCH, F.R.S.

TUESDAY, March 18th.

INSTITUTION OF CIVIL ENGINEERS.

8 p.m. Ordinary Meeting. Paper to be read with a view to discussion: "Lough Erne Drainage." By JAMES PRICE, Jun., M.I.C.E.

WEDNESDAY, March 19th.

CIVIL AND MECHANICAL ENGINEERS' SOCIETY.

7 p.m. Paper to be read: "Gold Mining in Merionethshire." By H. C. PAXON, Stud.I.C.E.

ROYAL METEOROLOGICAL SOCIETY.

7 p.m. Ordinary Meeting. Papers to be read: "A Brief Notice respecting Photography in relation to Meteorological Work." By G. M. WHIPPLE, B.Sc. "Application of Photography to Meteorological Phenomena." By WILLIAM MARRIOTT, F.R.Met.Soc.

SOCIETY OF ARTS.

8 p.m. Ordinary Meeting. "Commercial Geography." By J. S. KELTIE.

THURSDAY, March 20th.

CHEMICAL SOCIETY.

8 p.m. Lecture: "The Evidence afforded by Petrographical Research of the Occurrence of Chemical Change under Great Pressure." By Prof. JUDD, F.R.S.

INSTITUTION OF ELECTRICAL ENGINEERS.

8 p.m. Ordinary General Meeting. Paper to be read at conclusion of the Discussion on Messrs. Swinburne's and Esson's Papers: "Alternate *v.* Continuous Currents in Relation to the Human Body." By H. NEWMAN LAWRENCE, Member, and ARTHUR HARRIES, M.D.

FRIDAY, March 21st.

PHYSICAL SOCIETY.

5 p.m. Papers to be read: "Villari Critical Point of Nickel." By HERBERT TOMLINSON, F.R.S. "Bertrand's Idiocyclophanous Prism." By Prof. SILVANUS THOMPSON, D.Sc.

ROYAL INSTITUTION.

9 p.m. Evening Discourse: "Electro-magnetic Radiation." By Prof. G. F. FITZGERALD, F.R.S.

The Electrician.

Published every Friday. Price Fourpence; Post Free, Fourpence Halfpenny.
Editorial, Publishing and Printing Offices:

SALISBURY COURT, FLEET ST., LONDON, E.C.

Telephone No. 2714. Telegrams: "ELECTRICIAN NEWSPAPER, LONDON."

All Communications to be addressed to "THE ELECTRICIAN," *Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to* "THE ELECTRICIAN."

All letters intended for insertion in "THE ELECTRICIAN," *or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

"THE ELECTRICIAN" *is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.*

"THE ELECTRICIAN" *is on sale at the railway bookstalls throughout the United Kingdom on Friday morning, and can be obtained of all Booksellers and Newsvendors; or direct from the Publishing Offices as above.*

SPECIAL NOTICE.

Owing to the increase in the number of pages of "THE ELECTRICIAN," in order to partly cover the increased postage, we have been compelled to revise the rates for Foreign Subscriptions, which are now as follows:—

	3 months.	6 months.	12 months
For Foreign Parts and Colonies:—	s. d.	s. d.	s. d.
Within Postal Union	6 6	12 6	24 0
Aden, Borneo, Ceylon, China, India, Japan, Java Labuan Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7 6	14 6	28 0
The rates for the United Kingdom remain as follows:—	5 0	10 0	19 6

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to the office.

TRADE ADVERTISEMENTS *intended for the current issue must be handed in not later than First Post on Thursday morning.*

SMALL PREPAID ADVERTISEMENTS *(for Rates see page xv.) are accepted up to 4:30 p.m. on Thursday.*

TECHNICAL PRINTING.

"THE ELECTRICIAN" PRINTING AND PUBLISHING COMPANY (LIMITED) *beg to inform Electricians, Electric Light Engineers, &c., that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

"THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK.

Royal 8vo, 5s., postage extra.

Early in each year is issued "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The Directory was established in 1883, and the 1889 Edition consisted of more than 600 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with popularly-written Biographical Notices of the leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

The issue for 1890, which is still further enlarged and improved (making 850 pages), is NOW READY. Orders should be forwarded at once to the Publishing Offices, Salisbury-court, Fleet-street, London, E.C.

THE NATIONAL ELECTRIC LIGHT ASSOCIATION.

It is to be regretted that we have in England nothing to correspond with the American National Electric Light Association. This rapidly-growing society, which has just held its eleventh convention at Kansas City, performs the same function in the advancement of the electrical industry that the British Association does in the advancement of pure science. These Associations have, in fact, many points in common. Each convention lasts for about a week, and is held successively in various parts of the country. Good fellowship is promoted among the members by various kinds of social entertainment, while the numerous Papers read at the meetings afford the opportunity for a most valuable interchange of ideas between men drawn from all quarters. Each Association appoints several special committees to consider matters of importance, and to report thereon to the next meeting. The American Association is, however, far more commercial in character than either the British Association or the Institute of Electrical Engineers. Its delegates are actively engaged in electrical industry, the Papers read are very practical in character, and the resulting discussions straightforward and devoid of abstract theory. If busy men can find time to come together in a country of such extent as America, it is strange we have not yet practically

ASPINALL'S ENAMEL

COPY OF LETTER JUST RECEIVED AT NEW CROSS.

A Leading and Well-known Electrician writes:—

"HAVING used your **ENAMEL** considerably for various purposes, I find that it has **GOOD INSULATING PROPERTIES FOR ELECTRICAL WORK**, answering the purpose better than the usual Insulating Compounds in use, *which do not give such an appearance or finish as your* **ENAMEL.**"

Sold everywhere, in Tins; or Post Free, 7d., 1s. 6d., and 3s.; for Baths, 9d., 1s. 9d., and 3s. 6d. from

Works: LONDON, S.E. REJECT WORTHLESS IMITATIONS.

AS AN INSULATOR.

THE GENERAL ELECTRIC CO., Ltd.

(G. BINSWANGER, *Managing Director*)

(OF LONDON AND MANCHESTER)

recognised the possibility and importance of a similar association here. This might be done by the establishment of an Electrical Engineering Section of the British Association. The formation of an Electrical Section of the London Chamber of Commerce is certainly a move in the right direction, although such a body is too local to be altogether satisfactory.

The commercial value of the social element of such an Association consists in its tendency to promote harmony among rivals, and to lead, wherever possible, to the consolidation of interests. The committee appointed to inquire into the possibility of harmonising insurance and electric lighting interests in America has led to important results in connection with mutual insurance, and the proposed establishment of a standing committee, working in harmony with the insurance people, to draw up a uniform code of rules, and to constitute a body to whom disputed questions might be referred. One of the committees was appointed to consider the question of underground conduits. The great importance of this subject is such as to merit similar recognition from our own electrical societies. The committee charged with the duty of memorialising Congress with the view of bringing about free trade in copper seem likely to succeed in their efforts, and an instance is thus given of the political advantages arising from such an Association.

The report of the committee on the standardisation of potentials illustrates a tendency peculiarly American. In England manufacturers are still too willing to consider the wants of small isolated installations, and to make dynamos having outputs in volts and amperes specified by the buyers. In America, where central stations are more common, the tendency for a long time has been to produce only certain types of machines, converters, lamps, &c. Great advantages result to both buyer and seller from this process of standardisation. For instance, if a firm only makes dynamos of certain fixed sizes, the manufacture is rendered cheaper and the parts of the machine are replaceable, and can be renewed at a cheap rate. As electrical business increases it can scarcely be doubted that it will become necessary to manufacture machines and lamps to work at a few standard potentials; and English electrical industry would be advanced by promoting a conference of manufacturing firms with the object of coming to an agreement on this matter. The Special Committee on Potentials have now reported that the two leading American electric railway companies have agreed to work with a uniform potential of 500 volts, and that in all probability this potential will become the standard all over the States for street railway companies. The fact that the committee, while recommending electric light companies to add to their business by furnishing motive power to street railroads, point out the fallacy of the idea that the same machines may be advantageously used for both purposes, lends fresh evidence in favour of the standardisation of potentials, since the reserve power for one service can be easiest utilised for the other when there is a simple relation between the potentials used for the two systems.

The fact that electrical industry is now in a state in which it is more promoted by minute attention to details, and by the economisation of methods, than by the discovery of new principles, was brought out in several of the Papers. The days of fancy profits are quite gone. Competition has rendered the economical details of machine construction of far more importance than the type of design. The Papers on carbon tests and waste in arc light carbons brought out the importance of choosing right material, and of being as saving as possible in its use. The Paper of Mr. CARPENTER SMITH on a universal system of central station accounts contains many suggestions of practical value. Some of these are unnecessary for English firms, who, as a rule, attend to the small items of expense more carefully than is the case across the Atlantic; but the need of detailed accounts should be readily admitted now that common-sense business principles rule electrical industry. The advantage of keeping such accounts is twofold. By comparison of the amount of each item of expense from month to month a firm can detect any "leak in the business" and remedy it. Much of the matter contained in such accounts could, moreover, be divulged, without personal loss, at meetings of the National Association; so that it would be possible for each firm, by comparing its accounts with those of others, to discover where unnecessary expense was incurred.

Two important Papers by Prof. HOUSTON and Mr. LOCKWOOD dealt with the pressing subject of safety. The PRESIDENT, while condemning the present sensational agitation in America in connection with this matter, ventured the statement that the public had a kind of right to expect that the number of serious accidents accompanying the introduction of electrical industries should be less than those incurred in the introduction of steam and gas, since safety devices should keep pace with general development. Prof. HOUSTON, while fully admitting the danger when insufficient precautions were adopted, stated that the danger depended not on low or high tension, or on using direct or alternating currents, but on the methods of insulation employed, and the use of safety devices. He laid special stress on the fact that good methods of insulation and careful work meant good service; and urged the great importance of the adoption of more numerous safety devices. The Paper of Mr. LOCKWOOD showing how to make arc circuits safe, is naturally not of so much interest here as in America. The methods of continuous test proposed are, however, of great value, and are suggestive of modifications for other circuits. The important Paper of Mr. SPRAGUE has already been placed before our readers. The scope of the matter discussed by the Association was further widened by the presentation of valuable Papers on the economical generation of steam for electric light stations, on the steam engine, and on the construction of central stations. The inclusion of matter of a purely engineering nature is a good feature of an electrical association which might with advantage be reproduced in our own electrical societies.

OBITUARY.

WILLIAM HENRY SNELL.

It was our sad duty last week to announce the death of the Editor of *The Electrician*. Born on November 6, 1858, William Henry Snell showed in early life a natural aptitude for his future career. His early work in his native town of Tiverton was unconsciously the foundation of the success which he afterwards attained in the electrical profession. He received at Blundell's School the foundation of his general education. Not enjoying at any time robust health, he was in a measure thrown on himself, and developed a liking for physical study and research. Before he was 20 years of age he qualified as a science teacher at Kensington, and commenced teaching chemistry in Tiverton. He was also connected with the Literary Society of the town. In writing essays for this, and in contributing to the *Tiverton Gazette*, he no doubt cultivated the incisive style of writing peculiar to him. About this time he commenced original research in electrical matters, making most of his instruments himself. These experiments were continued for about three years, finally culminating in 1882 in inventions in connection with the microphone and telephone. He then came to London, but not being successful in exploiting these inventions, he turned his attention to the general study of electric lighting and the transmission of power, and entered the Hanover-

Digitized by Google

square School of Electrical Engineering. He soon took the foremost place amongst the students, winning the confidence of the instructors, who entrusted him with special original work. On leaving this institution in 1883 he took the highest certificates.

His first entrance to practical work was made with the Cunard Company, to whom he was the first and only chief electrician. Here his extensive knowledge and originality were at once apparent. He reorganised the system of ship lighting, saving both money and time and increasing the efficiency of the service. In 1884 he left the Cunard employ and returned to Tiverton. During the next six months he studied alternating-current distribution, and when he returned to London in June, 1885, read a Paper entitled "The Calculation of Mains for the Distribution of Electricity," before the Society of Telegraph Engineers and Electricians, gaining the Paris premium. This Paper at once stamped him as a man of more than ordinary ability. In the same year he assisted Prof. G. Forbes in some important calculations in connection with the distribution of electric light over large areas. These calculations were subsequently embodied in Prof. G. Forbes' well known Cantor Lectures of that year, and were made use of in evidence before a Select Committee of the House of Lords in May, 1886. About this time he invented, in conjunction with Messrs. Sharp and Kent, a virtual resistance for alternating currents. His name also figured in connection with the Kapp and Snell transformer.

In 1886 he joined the staff of *The Electrician* as assistant editor, after being for a few months a member of the staff of *Industries*. In 1887 he was appointed editor-in-chief of *The Electrician*, and here he found a congenial sphere of action for his great energy and abilities, the columns of this journal testifying how well he fulfilled the functions of this onerous and responsible position. Far from strong at any time, the stress of work soon began to tell on him, and early in the summer of last year signs of physical weakness began to show themselves. Nevertheless, he bravely stuck to his post, in spite of the urgent entreaties of all his friends, until the autumn. He then, acting under medical advice, sought rest and change at Matlock. Here he still further declined in strength, and it was then decided to try what the air and loving care of home would effect. It was, however, all to no purpose. He died on Wednesday, the 5th instant, passing quietly away, and was buried on Monday, the 10th, in the family vault at Tiverton.

Although forming but a small portion of his writings, the following signed contributions to *The Electrician* may be mentioned:—"On Resistance Coils for Large Currents," "Multiple Main Systems," "Ship Lighting by Electricity," "Alternating and Induced Electromotive Forces."

He was a member of the Institution of Electrical Engineers, and of the Physical Society, and he served on the Committee of the Electrical Trades Section of the London Chamber of Commerce.

THE INSTITUTION OF ELECTRICAL ENGINEERS.

SOME POINTS IN DYNAMO AND MOTOR DESIGN.*

BY W. B. ESSON, MEMBER.

(Continued from page 452.)

8. The Load to be Carried by Armatures.

Assuming that a machine is properly designed, a position can be found for the brushes where the sparking is *nil*. If, on the other hand, the machine is badly designed, or if the current carried by the armature is too great, a sparkless collection will be found impossible from the excessive distortion produced by the armature field. There is for every machine a certain limiting number of ampere-turns which the armature can carry beyond which we cannot go without effecting some radical alteration in the design.

Now it is manifestly of the very greatest importance to know to what extent an armature can be loaded for a given field. It will be understood that the cross induction—that is, the lines of force which can be induced by the armature winding—depends upon the number of ampere-turns on the armature, and upon the magnetic resistances of the various parts which make up the cross circuit. Undoubtedly the induction follows the same law for the cross as for the forward circuit, though it is difficult to determine with accuracy either its magnitude or direction. But we know that by far the largest portion of the resistance is encountered in the air-gap, and that increasing the length of the gap diminishes almost in inverse ratio the cross induction. We know also that the cross induction depends on the width of the air-gap, for the greater the cross-section of the gap, the greater the cross induction for a given cross-section of armature core and a given magnetising force. It depends also, but to a less extent, on the induction in the core.

The forward induction we can give to a machine may be considered as proportional to the cross-section of the armature core; for if the magnets are large enough, with sufficient magnetising force, we can always in normal types get an induction of 16,000 to 17,000 C.-G.-S. per square centimetre.

Now the distortion of the field depends upon the ratio of the cross to the forward induction. In actual machines we have not, of course, two sets of lines crossing each other, but the tendency to produce a cross induction is manifested in a distortion produced in the forward lines. It is to prevent the sparking which would ensue, due to this distortion, that a lead is given.

The cross induction may be reduced in double-magnet machines by thinning down the magnets as shown in Fig. 3. This illustrates a type of magnet I designed in 1884, which gave first-class results, to the great surprise of many who believed that no good effects could be obtained without massive pole-pieces, irrespective of the configuration of the magnetic circuit otherwise. For the reasons given in Section 3, it is undesirable to reduce the section of single-magnet machines with this object. Another plan for reducing cross induction is in making the air-gap increase from the crown of the poles towards the tips, as was done by Messrs. Paterson and Cooper in the Lumley machines before I joined them, and as is done in some of the Manchester machines for another purpose.

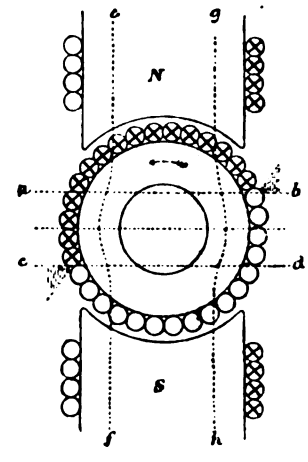

Fig. 19.

As both forward and cross induction are proportional to the length of the armature, we need not consider that dimension here, but simply confine ourselves to the cross-section of the armature and poles as shown by the several drawings. A lead being given to the brushes, it will be observed that the convolutions lying between the two horizontal lines *a b* and *c d*, Fig. 19, directly oppose the forward induction along *e f* and *g h*, since the current flows in them in the opposite direction to the current round the magnets. The lines of force which would be sent in an opposite direction may be called the backward induction. This, *per se*, is of little consequence, as it can be compensated by additional turns on the magnets, but the distortion of the field to which its existence is due is of enormous importance.

It is not my intention to take up time with any calculations respecting the actual number of cross lines which would be induced by the current flowing in the armature, or to try and map out the exact distribution of the field as modified by cross induction. For the present I will be content with the statement—which is, of course, open to criticism—that, roughly, the cross induction is proportional to the ampere-turns on the armature and to the width of the poles, measured parallel to the direction of rotation, and inversely proportional to the length of the air-gap, *i.e.*, the distance between the polar surface and the surface of the armature core. Calling A_2 the ampere-turns on the armature, w the width of the air-gap, and l its length, the tendency to induce cross lines is measured by $\frac{A_2 w}{l}$; and since the forward induction is proportional to the radial depth of the core r for all sizes of machines, the ratio between the above value and r should be similar. In

* Read before the Institution on February 20, 1890.

Digitized by Google

other words, the ampere-turns which can be carried by the armature are proportional to the radial depth of the core and to the length of the air-gap, and inversely as the width of the pole; whence

$$A_2 \propto \frac{r\,l}{w}.$$

For the purpose of showing to what extent some such relation as exhibited obtains in the machines now made, I have given in Table II. the dimensions of several taken at random. In the first

column after the names of the dynamos comes the outside diameter of the armature core, which does not enter into our expression. Next come the ampere-turns carried, followed by the radial depth in centimetres, with both of which we have to do. In column IV. is given the angle in degrees embraced by each pole, while columns V. and VI. give the length of the air-gap and width of the pole. In column VII. is given a coefficient by which the right-hand side of the equation must be multiplied, in order that for the sign of proportionality we can in each case substitute equality. According to the proposition put forward this coefficient ought to have the same value in all cases. The agreement is marvellous when we remember that in machines of the same size we have to vary the load considerably to suit different outputs, and that in the examples given the saturation may vary considerably. The disturbance due to cross induction bears about the same proportion in all; the similarity in this respect being, in fact, remarkable for machines so dissimilar otherwise. The machines Nos. 7 and 9 have iron wire cores, but Mr. Kapp has kindly given me the equivalent dimension of the radial depth were plates employed instead, and this is what appears in column III. The machine No. 4 is given because it is the one which departs most from my equation. The ampere-turns on the armature are here so few—that is to say, there is so little copper and so much iron—that I at one time suspected it of being the very machine which Mr. Crompton confesses to having designed during Mr. Kapp's absence at Vienna.* In the machine No. 8 the coefficient has been since reduced by narrowing the poles. About the motors Nos. 13, 14, and 15 I shall have something to say presently. In these the edges of the poles are curved along their lengths, hence the two angles in column IV. The coefficient is calculated from the mean width.

Inserting what appears to be the mean value in column VII., we have for the ampere-turns which may be carried by an armature the expression,

$$A_2 = \frac{r\,l\,85{,}000}{w},$$

which may prove very useful until we get something more exact. We have been taught by experience that diminishing the ampere-turns, increasing the radial depth, increasing the air-gap, or diminishing the width of the poles, reduces the distortion and cures its attendant evil of sparking. The equation states the same thing in another way, for it tells us that the ampere-turns may be increased in proportion to the radial depth and to the length of the air-gap, and inversely as the width of the poles. I do not wish for a moment to dogmatise on this subject. It is not pretended that the expression is complete, as there are doubtless many factors upon which the load depends. Amongst these are, obviously, the number of sections of the armature, the shaping of the pole-pieces, and the general configuration of the magnetic circuit. But the equation is at least a guide, and if the coefficient 85,000 is not exceeded, the machine can certainly be made to run without sparking. The expression applies equally to armatures with more than two poles, only in the case of these the ampere-turns given by it must be multiplied by the number of pairs of poles.

When speaking of the radial depth being increased it is of course assumed that there is the same induction per square centimetre in the increased section of the core. Again, increasing the air-gap is not supposed to diminish the induction, as additional magnetising force must be provided to keep it up to its original value. We conclude, then, that if the output of a machine of given carcase dimensions is to be increased—or, in other words, if the ampere-turns on the armature are to be greater—the tendency to increased cross induction must be counteracted by increasing the resistance of the air-gap. Some will doubtless be astonished to hear that greater output necessitates increased magnetic resistance.

Mr. Ravenshaw has a rule to the effect that in order to prevent sparking, in cylinder armatures the ampere-turns must not exceed 35 times the total area of the core in centimetres, or in drum armatures, assuming the same induction per square centimetre, 70 times the area. The rule has been applied to the construction of several types of two and four-pole machines, but it does not seem to me universally applicable, since the number of ampere-turns allowable depends not only on the area but on the relation of the two factors which make up the area.

Practical men must have rules of some kind. Without them their practice could not be continued for a single day. These rules, written or unwritten, are the results of experience which have been aggregated into some kind of applicable shape, but justification for which it would often be difficult to find on purely scientific grounds. We have to make our rules as we go along, engineering intuition and empiricism leading the way, knowledge and scientific accuracy following. We can speak with authority regarding the utility of a formula which we would be ill prepared to justify scientifically. It is because the rule here given has proved useful to me that I venture to suggest its use to others.

Regarding drum armatures I have not been able to get such full information; but in Table III. are given the diameters and ampere-turns on the armatures of some well-known machines. There seems to be little agreement, at first sight, between the diameter and the ampere-turns; but if these are plotted as abscissæ and ordinates respectively, it will be found that a straight line can be drawn through the intersection of the axes, giving a very fair mean of all the points save 5 and 7, which are abnormally high. The relation denoted by this line is A_2 = diam. in centimetres × 570. It will be understood, of course, that the induction may be very different in these armatures, as well as the ratio between the external diameter and central opening. If we take the latter as ·4 of the diameter, the ampere-turns are 1,900 times the radial depth of the core, in centimetres.

9. MAGNETISING FORCE REQUIRED TO COMPENSATE THE BACKWARD INDUCTION.

The weakening of the field by the current flowing in armatures wound on the Hefner von Alteneck principle has been studied by Drs. J. and E. Hopkinson; but from the fact that the lead upon which the weakening depends is, in Gramme-wound armatures, much greater and to a large extent indeterminate, it follows that, in designing, some approximate rule must be employed to fit the types of machines in which these are employed. We may estimate the effect of weakening in two ways: first, we may excite the magnets with a constant current, and measure the fall of E.M.F. due to the armature current; or, secondly, we may, by increasing

* *Jour.* Soc. Tel. Engrs., Vol. XV., 1886, p. 546.

Digitized by Google

the magnetising force, keep the E.M.F. up to the same value when a current flows as when the machine is working at no load, measuring the ampere-turns required to effect this compensation. The latter is the proper course to adopt, since, having pre-determined the magnetising force required for the induction in the armature at full load, on the assumption that there are no disturbing reactions, we wish to know what addition is to be made to the force so determined. The weakening of the field is much greater in cylinder than in drum machines, owing to the greater lead required to obtain a sparkless collection; accordingly the magnetising force necessary to compensate the backward induction must be greater for cylinders than for drums. Its actual value depends, necessarily, on several things besides the ampere-turns on the armature, such as the degree of saturation employed, the ratio of armature to field section, the shape of the pole-pieces, and the magnitude of the stray field. The particulars relating to the degree of saturation, the sections, stray field, &c., of the Phœnix machines have already been given, and from actual practice we find that there has to be added to the magnetising force, in order to compensate the backward induction in these machines, ·33 of the ampere-turns on the armature. By the ampere-turns on the armature is meant, as already stated, the product of the number of external conductors and half the total current. This is for a single horse-shoe machine. If there is a divided magnetic circuit constituted by two horse-shoes, with their like poles butting, the number of ampere-turns here given has to be wound on each horse-shoe.

I have met with some very curious rules for determining the compensating turns. These generally take the form of adding to the magnetising force determined for the required induction at full load such additional ampere-turns as will increase the induction about 5 per cent. It is assumed that at full load the E.M.F. will be as desired, the 5 per cent. extra being for compensation. This method is, of course, incorrect, for the magnetising force added should be for a given machine some function of the armature windings. I believe that for most Gramme-wound machines the value of the compensation coefficient here given will hold good. The compensation coefficient for drum machines I have not yet been able to determine.

10. Total Magnetising Force.

To the magnetising force required for a simple magnetic circuit as given in 1, we have to add the force required to compensate the backward induction, as given above. The equation for the magnetising force now becomes for cylinder machines—

$$A_1 = Lf\left(\frac{N}{a}\right) + L_1 \cdot 8\,{}^{v_1}_{a_1} N + L_2 f\left(\frac{v_2 N}{a_2}\right) + L_3 f\left(\frac{v_2 N}{a_3}\right) + \ldots + \cdot 33\, A_2,$$

where A_2 is the number of ampere-turns on the armature.

If the machine is to be shunt-wound, and N is the induction corresponding to the E.M.F. at full load, A_1 gives the ampere-turns on the shunt. If it is to be compound-wound, and N is the induction at full load, A_1 is the number of ampere-turns on the series and shunt windings added. The ampere-turns for the shunt alone are obtained by substituting for the induction at full load the induction on open circuit, the armature coefficient being of course here omitted. As a matter of fact, the value of v_2 increases between 0 load and full load, but for reasons already given this may in the calculation be neglected.

If the series coils are connected in series, to get the number of compensating turns on each horse-shoe we have only to multiply the external conductors on the armature by ·165. It may be mentioned in passing that in the Phœnix dynamos the total series convolutions for ordinary compound machines are uniformly ·31 of the convolutions on the armature; this, multiplied by the current, being the magnetising force necessary to overcome the resistance of the armature and the series coils, and to compensate the backward induction. It will thus be seen that rather more convolutions are required for the latter purpose than for the former, and I think that in most dynamos of medium size the relation is very similar. The only extraordinary relation I know of is in the Victoria machine, where the compensating turns, instead of being a little greater than the turns required to overcome the resistance of the armature and series coil, are three times as great.

11. Working Temperature.

The ultimate rise in temperature of coils wound with double cotton-covered wire, varnished on the exterior, is, approximately, in degrees Centigrade,

$$C^0 = \frac{W\ 355}{S},$$

where W is the rate at which energy is dissipated in watts, and S the cooling surface in square centimetres. If, for the latter, we substitute square inches, S_1, the equation is

$$C^0 = \frac{W\ 55}{S_1}.$$

The coefficients have been obtained from practice, but they are liable to some uncertainty. In the cases from which they have been derived the coils were wound on formers of sheet iron, which fitted close to the magnets. These formers were fitted with brass end flanges, and in the spaces between the flanges and the wire, also between the body and the wire, was a thick layer of insulating material. The surface of the end flanges is not included as making up S or S_1, nor is the inside surface of the former next the magnet. Though insulated so well thermally, there is certainly a flow of heat towards the interior of the magnets and towards the end flanges, so that, as a matter of fact, the virtual cooling surface is greater than given above. Its value it is, however, difficult to determine, while the above equation is approximately true for machines of medium size, and may be used for all cases in which the coils do not exceed 2½ or 3 inches in thickness.

For armatures—which in rotating induce a current of air—the equation is different, and the coefficient given above may have a much lower value, according to the velocity and ventilation. For armatures the surface velocity of which is 50ft. per second (3,000ft. per minute), and the exterior diameter of the core 1½ times the interior, the length being about equal to the diameter, the rise is, approximately,

$$C^0 = \frac{W\ 225}{S},$$

or

$$C^0 = \frac{W\ 35}{S_1},$$

accordingly as the surface is taken in square centimetres or square inches. Here the whole of the cooling surface inside, outside, and at the ends is counted, W being the total watts dissipated in both electrical waste and hysteresis. The latter must, under no circumstances, be neglected, as it may reach 20 per cent. or more of the total. In giving the above equation, it should be stated that the armatures of the machines which furnished the results are closed at the commutator end, except at the periphery, where a draught of air through the centre from the pulley end is expelled. For slow-speed machines the coefficient is necessarily higher, and a larger surface must be allowed, or special means adopted, in the shape of vanes or blades, to force a draught through the armature. Experience only can be the guide here.

Considerable difference of opinion exists with reference to the temperature rise which should be permitted in dynamos. The rise of about 11° C. allowed by the Admiralty is admitted by all engineers to be absurdly low; while, on the other hand, the machines sent out by some manufacturers get at their normal output dangerously near the temperature at which the insulating material would become useless. We have to steer between these two extremes, working far under the critical temperature, but, at the same time, not making machines too costly on account of the excessive surface allowed. It will be observed that from the manufacturer's point of view the settlement of this point is of great importance, since a competitor, by allowing a greater temperature rise, may put in a machine of less weight, and therefore less costly, though not necessarily less efficient.

In any case, the ultimate temperature of the machine ought not to rise above a certain value, whatever the temperature of the room in which it works. In my opinion, an ultimate temperature of from 70° to 75° C. may be permitted with perfect safety, but this should not be exceeded. Independently of the ultimate temperature, the rise in working should not be too great, and accordingly we have in the Phœnix dynamo fixed this limit at from 30° to 35° C. Machines working in atmospheres up to 35° C. have a cooling surface, therefore, which will give in continuous working a rise of 35° C.; when the temperature is higher the cooling surface is increased, so that the maximum temperature does not exceed 70° C., the limit given. It will be seen from the formula that, for a rise of 35° C. in the magnets, the cooling surface is 10 square centimetres (1·56 square inches) per watt.

For armatures having the proportion stated, the surface requires to be about 7·3 square centimetres (1·13 square inches) per watt; but here it is less easy to formulate rules. Both interior and exterior surfaces are ventilated by the motion, the former generally being of a broken character, which aids the cooling. The temperature of these surfaces does not measure the temperature of the bottom layers of wire or of the armature core itself; and when I speak of a temperature of 70° C, I mean, of course, that of the hottest part. The difference of temperature between the interior of the core and the outside surfaces, in a machine of given carcase dimensions, depends on the gauge of wire with which the armature is wound. Obviously, the difference of temperature required to produce a given flow of heat depends upon the thermal resistance encountered, and, therefore, on the number of layers of badly conducting substance, in the shape of cotton covering, through which the flow takes place. For this reason, an armature wound with one layer of coarse wire requires a less cooling surface per watt to keep down the internal temperature than an armature wound with fine wire, even if the mass of copper is similar. In

Digitized by Google

practice, allowance for this is made by working the small-gauge wires to a less current-density. On account of the flow of heat being obstructed by badly conducting substances, armatures with cores constructed of wire always get hotter inside than those with plate cores.

Of course, it will be understood that the coefficient given for the rise of temperature will be greater for those armatures in which the central opening in the core is less than two-thirds of its external diameter. Where, for instance, it is half the external diameter, the inside radiating surface is diminished to three-fourths of that specified, and the temperature rise will be proportionally higher, unless a stronger draught of air is sent through the centre of the armature.

(To be continued.)

THE PRACTICAL WORKING OF THE ELECTRICAL SUBWAYS OF NEW YORK CITY.*

BY WILLIAM MAVER, JUN.

The customary reply to an inquiry as to what is the best arrangement for an electrical subway is, "Build a tunnel under the streets and place the wires on the walls within easy access of workmen, and into such a tunnel put also the gas and water mains, &c." Assuming that this would be a satisfactory solution of the underground question if it could be arranged, let us consider what the cost of such an arrangement would be. It has been estimated that a subway suitable to contain all the electric wires, gas and water mains of New York city would cost $430,000 per mile; and if such a tunnel were to be built throughout the entire route of the now existing electrical subways of New York city, the bill would foot up to nearly $30,000,000. This amount, it will, I think, be generally admitted, is virtually prohibitory of any such subway at present; and if that is the case the fact will perhaps make those who have had preconceived ideas in favour of a universal tunnel scheme more tolerant of the electrical subways we have, the practical working of which I am to endeavour to describe this evening.

It is very far from my intention to go into a history of the opposition offered by the different electrical companies to placing their wires underground. I can imagine, however, that there are many persons who, if told that the telephone, telegraph, high and low tension electric-light circuits, and even the "deadly" alternating circuits are to-night in this city working successfully underground in the same streets and on the same side of the streets, would reply, "If they really are working successfully there they have no right to be."

In New York city to-day there are 73 miles of electrical subways, and 1,017 miles of ducts. In these ducts there are 10,906 miles of telephone wire, 945 miles of telegraph wire, including fire-alarm telegraph wires, and 457 miles of electric-light wires. These subways have a capacity for about 45,000 miles of telephone and telegraph wires and 2,000 miles of electric-light wires.

Conduits.

There are in the New York electrical subways eight different conduit systems—namely, the Dorsett, the Wyckoff, zinc tubing in hydraulic cement, sheet-iron cement-lined pipe, wrought-iron pipe in hydraulic cement, wrought-iron pipe in asphaltic concrete, the Edison iron tube, and the Johnstone sectional cast-iron conduits.

The Dorsett system consists of blocks formed of a material the ingredients of which are pitch, coal tar, and fine gravel. The blocks are moulded, with tubular openings about 2½in. in diameter from end to end. The blocks are about 4ft. long and 1ft. cross-section. These blocks are placed end to end in the trench, and are joined together by pouring between the ends a liquid compound of pitch and tar, which speedily hardens. This compound is prevented from entering the ducts by sleeves, which are placed in each duct between the junction of every two blocks. There is about one mile of this conduit, containing 16 miles of ducts, on Sixth-avenue. It is used for telephone and telegraph conductors. This conduit was laid three years ago. So far as I can learn, it is in a fair state of preservation to-day—but not perfect; the blocks having in some instances sunk, and thus put the ducts out of alignment. It may be noted here that guide ropes, consisting of ¼in. tarred hemp, which were laid in these ducts when this system was constructed, to be in readiness when cables were to be drawn in, show plainly in numerous places signs of deterioration, said to be the result of dry rot, combined with the gases found in the ducts.

The zinc tube conduits are laid in 58th-street. The zinc tubing was intended to serve simply as a mould around which hydraulic-cement concrete was to be placed, with the expectation that when the zinc had corroded the tube formed by the solid cement would remain intact. About one mile of this conduit has been in successful operation for three years; but the difficulty attending *the construction* of a conduit formed in this way was so great, owing to the frailty of the zinc tube, which readily gave way under moderate pressure, that its use has not been further extended.

The sheet-iron cement-lined pipe conduits are made in single or multiple tubes of two, four, six or more ducts, as may be required, and in lengths of 8ft. The tubes are connected together by a ball-and-socket joint. These conduits are made as follows:—A sheet-iron tube 8ft. in length is held vertically; inside of the tube is placed a smaller brass tube, and semi-liquid cement is poured into the annular space between the brass and sheet-iron tubes. When the cement has solidified the brass tube is withdrawn. The cement tube is then ready for the subways. There are about 113 miles of ducts of this conduit in the subways, and during the coming summer it is expected many times this amount will be laid in New York City.

There are about 15 miles of creosoted wooden ducts in the subways known as the Wyckoff conduits. These ducts are formed of wooden piping similar to ordinary pump logs. There are lead-covered telephone cables in these ducts, and the action of the creosote upon the lead covering is being carefully watched. These ducts have been in operation for three years. I am informed that detrimental effects are noticeable in the lead-covering of the cables, which is alloyed with 3 per cent. of tin.

The bulk of the subway conduits consists of wrought-iron pipe laid in hydraulic-cement concrete. These pipes are 20ft. in length, and vary in diameter from 2in. to 3in. The thickness of the iron is ·217in. In laying all these pipe conduits, the bottom of the trench is first levelled to grade; planks are then set against the side of the trench to sustain it; a layer of concrete is then laid and rammed in the bottom of the trench; on this is placed a row of iron pipe, next a layer of concrete, then another row of pipe, and so on, until the desired number of layers is attained. There is placed over all a 2in. yellow pine planking, heavily creosoted, to protect the conduits against injury from picks, crowbars, &c.

The wrought-iron pipes are joined end to end by a coupling screw joint with a tapering or vanishing thread. By the use of this form of thread, I am informed, the rate of laying this pipe is increased 50 per cent. These tubes are delivered free from burrs, and have a smooth inner surface. The pipes are sometimes asphalted to prevent rusting; but should they in the course of time rust, it is expected, as in the case of the zinc tube, that the concrete will preserve the shape of the duct intact. There are close upon 550 miles of wrought-iron piping in the subways. The main reasons which have led to the extensive use of wrought-iron piping in the subways are its great strength, its adaptability to varying conditions of the street, and the rapidity with which it can be laid.

The subways are in many cases on both sides of a street, and, as a rule, the telegraph and telephone wires are assigned to ducts on one side of the street, and the electric light to ducts on the opposite side; but in numerous instances the electric light wires are operated in distributing ducts on the same side of the street as the telegraph and telephone wires, and without detriment to the latter.

Manholes.

Access is had to the conduits of the New York subways by means of manholes, placed at an average distance of about 1-25th of a mile apart. The manholes are, with a few exceptions, built of brick laid in concrete cement, with hydraulic concrete bottom. The outside of the walls is coated with cement, to prevent moisture and gas from penetrating. Access to the manholes from the street is had through the cast-iron head which is set on the brickwork, and which is provided with double covers. The upper or street cover weighs about 350 pounds. The lower cover is provided with a rubber gasket to prevent ingress of street water into the manhole. This cover is funnel-shaped, in order that any water which may enter through the upper cover may be drained away from the gasket. The lower cover is screwed down upon the gasket by a gun-metal bolt and cross-bar. The upper cover is loose upon its bearings.

Rodding.

The electrical subways of New York city, with the exception of the Edison system, are of the class known as the drawing-in-and-out systems. The first process in drawing a cable through a duct which is not easily accessible except at its ends in the manholes is obviously to provide a means of drawing in the cable. This is done by a process technically termed rodding, which consists of pushing rods through the duct from one manhole to the next. A rope is then attached to the end of the rod, and the rod is withdrawn, bringing the rope with it. This rope is then employed to haul in the cable. As some of the manholes are over 500ft. apart, and it would not be convenient to procure a continuous wooden rod of that length, rods of about 4ft. in length, fur-

* Abstract of a Paper read before the American Institute of Electrical Engineers, New York, February 18, 1890.

Digitized by Google

nished at one end with a screw, and at the other end with a screw socket, are used. These are placed in a bunch in the manhole, and are attached by the screws one to the other, as many as are required to reach to the distant end of the duct. The rods are then detached, as they are drawn out, by unscrewing the ends.

Drawing in Cables.

After the rope has been attached to the cable, the latter is then "threaded" through the duct. The manner of applying the force necessary to pull the cable through the duct depends upon the size and length of the cable. If it is a small cable, say 300ft. in length, it can be drawn in by two or three men. If it is a large cable, or if four or six small cables are to be drawn into one duct, as is frequently done, more elaborate drawing-in apparatus is used. This generally consists of some form of winch. The largest telephone cables are drawn in by a winch of special construction, in which the power is transmitted through the intervention of wheel gearing. As many as six electric-light cables, No. 4 B. and S. conductor, have been repeatedly drawn at once into a 3in. duct. As the weight of a No. 4 B. and S. lead-covered cable is, for 300ft., say 250lb., an idea may be obtained of the force required to draw in six such cables. I am informed that cables weighing in the aggregate 5,510lb. have been drawn at one time into one duct.

Methods of Distribution.

It is, of course, a comparatively easy problem to arrange an electrical subway for trunk-line circuits. The difficulty arises when the question of distribution of the current from the main conduits is to be considered. Distribution of the electric-light current is effected in several different ways in the New York subways. For street arc lamps the circuit is usually looped from the manhole to the lamp-post through a subsidiary iron pipe. For easy access to houses and to lamps in the middle of blocks, distributing ducts are laid above the trunk ducts as near the surface of the street as practicable, the average distance from the surface of the street being perhaps 18in.

The Johnstone sectional conduit has hitherto been the most extensively employed for this purpose in New York city. This conduit consists of sections of cast-iron ducts about 5ft. in length. The sections are placed directly above each other, and are held together when in position by removable clamp pins. The upper section rests in a groove in the lower section. Each section of the conduit is divided into from two to six or more compartments or ducts. the ducts being formed by removable partitions or slats held in position by suitable channels or grooves within the section. Opposite each house or every alternate house a handhole is provided in the upper section of the conduit. The handhole consists of a removable cover, about 2ft. in length, on the upper section, and the side of the section at this point is provided with a branch or spigot. This conduit is laid directly in the earth—not in cement. When it is desired to tap or loop the circuit, a 3in. iron pipe is run from the branch at the handhole to the basement of the house, or to the lamp-post with which connection is desired to be made. This iron pipe fits on to the spigot at the side of the conduit. Should the conductor which it is desired to tap be at the side of the section remote from the spigot, the intermediate partitions are removed to permit the passage crosswise of the connecting cable.

When a handhole has not been provided originally at a point where access is desired to a conductor in the conduit, the entire upper section is removed and replaced by a half section containing a handhole cover and spigot. These conduits are presumably made air and water-tight at the junction of the two sections and at the ends of the ducts, by the use of plumbers' putty. In view of the number of supposed opportunities for the entrance of moisture at these junctions, it would be naturally expected that this type of conduit would be in a chronic moist condition. Indeed, it has been predicted of it that the ducts would act as canals for the surface water, but, as a matter of fact, these ducts are almost invariably dry. There are two theories given to explain this fact: the first, that in reality the plumbers' putty makes an air and water-tight joint; the second, that if the joints are so imperfect as to admit water, they are quite capable of permitting its escape also. It must be said that this system has been found of much utility in the practical distribution of electric-light current in this city.

More recently a method of distribution in which wrought-iron pipes are used has been employed. This consists of a row of three or four iron pipes laid, like the Johnstone conduit, as near the surface as possible—in the earth, without concrete. Opposite every party wall, or, in other words, at distances of about 50 feet apart, iron boxes about 18in. square are placed. Then these boxes have removable covers. The ducts enter at the ends of the box, but do not pass through it. The boxes are provided with side openings also for the entrance of the subsidiary iron pipes. Access is had to these boxes also by the removal of the street paving and earth. This method of distribution has, like the one just described, been found satisfactory.

The Cables and Insulation used in the Subways.

In the telephone service in this city, the cables used are chiefly of the type known as the Patterson. This cable is constructed as follows:—Ordinary cotton covering is first placed around the wires. After the wires are cabled a lead covering is placed over them, and paraffin is then forced into the interstices between the conductors and lead covering. This cable has an electrostatic capacity of about 0·16 microfarad. The insulation resistance of the cable, laid and jointed in the subways, averages about 100 megohms. The longest stretch of cable used by the telephone company in the subways is seven miles. The greatest number of conductors in any one cable is 100 or 50 pairs.

The telegraph companies have thus far used chiefly for underground service Kerite, Okonite, Standard Underground, and Patterson cables. The Kerite and Okonite insulation, it is well known, are homogeneous compounds. These cables are not lead-covered. Of course, they could be. The Standard and Patterson are fibrous cables, and are lead-covered. Except in the vicinity of the underground steam pipes, the unprotected homogeneous cables have given uniform satisfaction. But, as might be expected, the effect of escaping steam upon them has been detrimental. Fortunately, the heated area in the vicinity of the electrical subways is limited to a portion of the down-town districts. Investigation has shown that the heat only reaches a harmful temperature in the neighbourhood of actual leaks in the steam pipes. Measurements of the temperature of a manhole in the worst section of the heated district have shown as high as 150° to 200° F. Since the starting of the blowers in this district to ventilate the subways, a noticeable decrease in the temperature is observable, and, inasmuch as the steam-heating company is achieving some success in its efforts to close up all leaks in the pipes, it is anticipated that the heat difficulty will be eventually removed from the subways. The users of the Standard and Patterson cables state that those cables are giving very fair service in the heated portions of the subways, although the high temperature, of course, lowers the insulation resistance of the cables. The average number of conductors in the telegraph underground cables is about 50. The size of the wire used is, as a rule, No. 16 B.W.G., and the outside diameter of a conductor, including the insulation, is $\frac{5}{32}$ of an inch. The insulation resistance of the Okonite insulation is about 2,500 megohms; that of Kerite 500 to 800 megohms, and that of the Standard and Patterson about 1,500 megohms, per mile for the thickness of insulation just mentioned. Outside of the injury to the cables due to the presence of the steam-heating pipes, no undue deterioration of the telegraph cables in the subways has been noted.

(To be continued.)

STANDARDISATION OF POTENTIALS ON STREET RAILWAYS.*

It was deemed advisable by the members of the committee to send out a circular to all railway companies operating their system of car lines by electricity, notifying them of the appointment of this committee, and asking not only their co-operation, but also drawing their attention to a number of questions that we desired they should reply to.

1. What system do you use?
2. What proportion of your cars are equipped with motors?
3. Do you generate your own electrical power, or are you supplied by an electric light station?
4. What proportion does your greatest average horse-power in use bear to the total horse-power of engines and boilers which you have installed?
5. What is the voltage or pressure of your generators?
6. Is there any other railroad in your town using an electric system? If so, what system do they use, and do you know the pressure at which they run?

We have received replies from 85 per cent. of all the electric street railway companies. They have, one and all, showed every disposition to give us full reports upon the questions that we have asked them, and have stated that they would afford us every facility that lay in their power, and that they desired us to convey to the National Electric Light Association their hearty endorsement of this plan.

Question 1.—Fully 90 per cent. of all the railways now in successful operation are operated under the systems controlled by the Thomson-Houston and Sprague Companies.

Question 2.—We find that at least three-fourths of the railways have equipped all their cars with motors, and that the sizes of the motors upon the cars vary from 7 1-2 to 15 H.P.

* Abstract of the Report of a Committee of the National Electric Light Association, presented at the meeting at Kansas City, February 1, 1890.

Digitized by Google

Question 3.—Only nine electric light companies have been brave enough to agree to supply the street railway companies with their power, although in nearly every case when the railway was in operation there was at least one central station company who could have contracted to supply the necessary current.

Question 4.—In all railways operating over fifteen cars only one-third of the total horse-power with which the plant has been equipped has ever been called for at one time. On all roads operating between five and fifteen cars the greatest average load has not reached 50 per cent. of the total horse-power, and upon smaller roads the average load has varied from 50 to 80 per cent. of the total horse-power. All roads that have met with heavy grades have raised the average very considerably.

Question 5.—We find that the potential varies from 220 to 800 volts. The greater number of companies, however, report using a potential between 450 and 550 volts.
